Amphibians and Reptiles of Nepal (*A&R of N*) joins the growing list of field guides, photographic atlases, and natural histories of the Asian herpetofauna. It is a totally different book from any of the other recent volumes on Asian herps, matching—actually exceeding—Zhao and Adler's *Herpetology of China* (1993) in total pagination. Weighing in at 2+ kg, it is a field guide for the laboratory or reading desk, certainly not for the backpack in Nepal's mostly vertical countryside. But Schleich and Kästle were not attempting to provide a guide for the hip pocket or backpack. Their goal was "to compile a summary of today's knowledge on Nepalese amphibians and reptiles." They have succeeded.

Of course, no book of this size and with multiple authors is without some shortcomings. In this case one problem is that the weight of the pages breaks the binding with minimal use. Others will be identified as I examine the different features of *A&R of N*, and I will also offer a few reviewer's laments expressing my desire for some things to have been done differently.

The herpetofauna of Nepal is modest, totaling 52 amphibian and 125 reptilian species (data from *A&R of N*): one salamander, one caecilian, 50 frogs, two crocodilians, 15 turtles, 39 lizards, and 69 snakes. The low diversity of the herpetofauna is not unexpected owing to Nepal's small size (140,400 km^2) and its mountainous landscape with a significant portion climatically unsuitable for herps. The editors note that only 3.17% of Nepal is habitable for amphibians and reptiles. While this precision of habitable area seems overstated and an underestimate (perhaps 31.7%?), the herpetofaunal Lebensraum is small. Nepal consists of a series of east-west stepwise bands of habitat, each of increasing elevation. The terai grasslands are shared with India. Next is a series of low hills that create multiple narrow valleys with a mixture of grasslands and dry evergreen forests. This is followed by a mountain range extending upward to about 2000 m; these mountains form the southern edge of the broad fertile midlands, formerly mainly forested and now largely farmed, with the mountains of the Fore Himalaya (2500–4000 m elevation) on their northern edge. Northward and upward of the Fore Himalaya is the Great Himalaya with landscapes largely inhospitable to herps. The habitable area for herps is also habitable for people and much of it has experienced human usage for hundreds of years. The impact has been increasing steadily since the end of World War II, with expanding human populations in the terai to midland areas because of malarial control and the immigration of Indian farmers. Trekkers arrived in the 1970s and as their numbers increased so did the demand for wildlife and forest resources. The Nepalese government and local conservation organizations recognized the situation and initiated programs to preserve habitats that accommodated the needs of residents and visitors. Even though the programs are not totally successful, they have preserved "wilderness" habitats for much of the wildlife. Preserves, such as the Royal Chitwan National Park, provide habitats for tigers, rhinoceros, and the recently described endemic *Rana chitwanensis*.

More species certainly will be discovered and the diversity of the Nepalese herpetofauna increased further. Two new agamid lizards are described in *A&R of N* and a few frogs and lizards are labeled as unknowns in the photographic plates. It was in Nepal that Alain Dubois recognized the complexities of the *Fejervarya limnocharis* complex; he found three species (*F. pierrei*, *F. syhadrenis*, *F. teraiensis*), two of them new, sympatric in the terai of central Nepal. Multiple Nepalese species likely hide today under a single name in other groups of amphibians and reptiles. In their advice to critics (= reviewers) paragraph, the editors identified four genera, e.g., *Calotes* and *Oriotiaris*, that contain more species than currently recognized. This phenomenon is probably common for most of the widespread South Asian species, because few systematists have examined local and regional variation in Asian species, and those that have quickly recognize a high level of regional speciation. A good example is Wüster's recognition of multiple species of *Naja* in South and Southeast Asia. It is our growing knowledge of the Asian herpetofauna and the expanding literature on this fauna that makes *A&R of N* useful. In addition to summarizing our current knowledge, it serves as a benchmark to assist our decisions on conservation and research priorities.

A&R of N follows the organization of the earlier compendium on the herpetofauna of North Africa by Schleich, Kabisch and Kästle (1995). With that volume, it shares many organizational features, the page layout, color plate quality and formatting, and publisher. The Nepalese volume, however, offers more topics, although similar treatment of the subject matter within the shared topical chapters. This volume also has a broader authorship; 12 authors are identified although I could match only eleven authors with chapters. Authorship is listed only at the beginning of each chapter and not all chapters have their authors identified. The chapters or sections and their authors are: 1) Introduction (authorship unidentified, presumably H. H. Schleich and W. Kästle); 2) The Environment (presumably Schleich and Kästle); 3) Amphibians and reptiles in Nepalese culture and economy (Karan B. Shah); 4) Snakebite avoidance and medical treatment (Klaus Kabisch); 5) Nepal's herpetofauna on a razor's edge between threat and conservation (Tirtha Maskey, Schleich and Kästle); 6) Species list with annotations (Schleich, Christiane Anders and Kästle); 7) Zoogeography of Nepalese amphibians and reptiles (Kästle, Schleich, Indraneil Das and Anders); 8) Special part - Detailed information

on Nepalese amphibians and reptiles (multiple sections devoted to accounts of the families, genera, and species of the herpetofauna). This section is multi-authored: Amphibia (C. Anders); Crocodilia (Maskey and Schleich); Testudines (Schleich and Kästle); lizards (Kästle, except *Draco* [Kalu Ram Rai], *Oriotiaris dasi* n. sp. [Shah and Kästle], *Sitana schleichi* n. sp. [Anders and Kästle], Scincidae [Valery Eremchenkoe]); Serpentes (multiple authors: Boidae including *Python* [Kabisch], Colubridae [Ulrich Gruber], *Coelognathus* and *Elaphe* [Notker Helfenberger], *Elachistodon westermanni* [Das], *Oligodon kheriensis* [Schleich and Kästle], Elapidae, Typhlopidae & Viperidae [Kabisch]); 9) Supplements (= Appendices); 10) Abbreviations and scientific terminology; 11) Literature references; 12) References for text figures; 13) Species index (with nine subsections). Andreas Diener is the listed author without chapter identification. Clearly, the contributions of Kästle and Schleich to this volume are substantial.

The substance of *A&R of N* begins with the second chapter "The Environment" (Note: the numbering of the chapters/sections is mine, not the editors'). This gives a concise introduction to landforms, climate, and life zones; it is not overly detailed but definitely adequate for those unfamiliar with Nepal. The third chapter offers a fascinating and brief introduction to herps in Nepalese religions and legends. It also provides an explanation of the various uses of amphibians and reptiles for medicine and food. The fourth chapter provides an overview of snakebite in South Asia with a focus on Nepal. It contains much information in a compressed presentation. I was surprised to discover that Russell's vipers were not implicated in any Nepal bite incidents, and that cobra and krait bites predominate; in contrast, Russell's vipers are responsible for the greatest number of bites and fatalities in the neighboring Indian state of Uttar Pradesh. This chapter also provides detailed first aid treatments for snakebite; this information is both unnecessary and dated (e.g., including cut and suction). The Nepalese audience requiring this information will not have access to this book and would potentially be harmed by some of the advice. The fifth chapter examines the conservation of Nepalese herps; while a broad brush review of the current situation, it contains a good history of conservation in Nepal and addresses both local use and trade in amphibians and reptiles.

The sixth chapter is "Species list with annotations." The annotations largely address distributional data and species misidentifications. These observations could have easily been incorporated in chapter eight, the taxonomic accounts. Zoogeography is the topic of Chapter 7. The presentation is mainly tabular, e.g., number of species in Nepal and adjacent countries, by elevation, by longitude, and so forth. This manner of presentation affords the reader a variety of distributional tidbits on each species or groups of species, although these factoids are more ecological than biogeographical. The authors begin their "biogeographic" discussion with an examination of centers of radiation for genera, each of which is implicitly accepted as a clade. The centers are subregions of biogeographic regions or realms that are explained in a subsequent section on distributional patterns. It is not clear in the centers or distributional sections how or why a species or genus is assigned to a zoogeographic subregion. The biogeographical analysis is descriptive and based on the *a priori* assignment of species to subregions, resulting in a chapter informative at a most general level.

Chapter 8 is the field guide portion of *A&R of N*. It is also the most extensive section of the book, totaling 915 pages. These pages are packed with information derived from the literature and recent fieldwork, and it is a section to be mined for natural history information on Asian species. It is also a chapter that frustrates me greatly because of data truncation. However, before outlining my frustrations, I must summarize the general organization of this section for readers unfamiliar with the earlier compendium on North African herpetology. Each group (class, order, family, etc.) contains a key if the group is not monotypic for Nepal. Each species account consists of up to 10 major sections (etymology, synonymy and vernacular names, identification, ecology and general behavior, reproduction, geographic range, systematics, subspecies, notes, references); the identification, ecology, and reproduction sections are further subdivided. Each of the higher categories has fewer sections and is notably brief. Page layout is double column; the right column is double the size of the left and is reserved mainly for text, the left column for figures. This page layout works well for the field guide portion where figures occupy most of the right column but is much less effective elsewhere where one third of each page is blank for many consecutive pages.

Text figures are black and white line drawings, functionally and, in most cases, attractively rendered. An idiosyncracy of the Schleich and Kästle compendia is that each page begins with a new Figure 1, thus there are hundreds of Figure 1s, tens of Figure 2s, and declining numbers of Figure 3 and beyond (15 figures on a single page appears to be the high). Legends are succinct and sufficient; they do, however, lack source information. That information is available in the "References for text figures" in the rear of the book. Schleich and Kästle have borrowed broadly from the herpetological literature and created many new illustrations. Each species commendably has its own spot distribution map, and each map is covered with a grid overlay. An additional and useful feature of the maps is that a smaller South Asian map lies below the Nepal map and displays the total Asian distribution of the species. Equally commendable, each spot can be identified by its position on the grid and reference to the alphabetical list of localities in the "Supplement" chapter. Additionally, the first section of the "Supplement" has a list of localities for each species. I applaud the editors on this much attention to mapping and providing the details on species occurrences and the localities. In spite of this massive effort, however, there is a problem that makes the distributional data less reliable or verifiable than it might be. The locality information, aside from that derived from the literature, may or may not be based on voucher specimens. Further, the editors provide no evidence that they checked the holdings of the world's major museums for locality data.

The textual sections of each account are overall data dense but with peculiar lapses. More attention is directed at the etymology of the scientific name and at vernacular names than at the synonymies. Each of the few synonymies checked (I used frogs because of the convenience and currency of Frost's *Amphibian Species of the World* website: http://research.amnh.org/herpetology/amphibia/index.html) lacked one or more primary synonyms. I did not locate an editorial statement that the synonymies were intentionally incomplete. The Identification (= Description) sections contain a broad range of characteristics and these are conveniently arranged in subsections. The presentation is also consistent within genera

and generally within major groups, thereby permitting a ready comparison between congeners. I find fault with two aspects of the Identification. First, it appears that much of the data therein is a composite from throughout the range of the entire species; this fault is particularly unfortunate because widespread Asian species are likely complexes and a summary of the traits in Nepal populations would have been most valuable. Second, the measurement section most commonly presents a maximum length of a male and of a female. Means and ranges are much preferable and should be derived from adult animals only. I also protest the use of only total lengths for snakes. I suspect that if I had a stronger ecological or behavioral interest that I would find similar faults with those sections; however, in my defense and as a commendation to Schleich and Kästle, the amount of information and its methodical organization for these topical areas far exceed that available in similar books.

I did not test the identification keys. They are laudably based solely on external morphology and, in most instances, on traits that can be counted, measured, or differentiated by naked eye and hand lens. Taxonomy and nomenclatural usage are variable in recency and explanation. Part of this variation results, I believe, from the asynchronous completion of the various taxonomic groups as well as the taxonomic inclinations of different authors. Based on the literature cited, some parts may have been completed in late 2000, others in late 1998 or early 1999. For example, the *limnocharis* complex of frogs is now widely placed in the genus *Fejervarya* not *Limnonectes*; the placement of some snake-eyed skinks in *Asymblepharus* has not yet gained wide acceptance (outside the former Soviet Union); and the elevation of the small bodied *Kachuga* subgenus *Pangshura* had not yet been published when *A&R of N* appeared; *Python* is considered a boid with no indication that the author is aware of literature addressing the differences of pythonids and boids.

A set of 127 tripartite photographic color plates separate the amphibian and reptilian taxonomic accounts. Many species are depicted with two or more images. The images at 5.5 x 10 cm are sufficiently large to reveal identification characteristics. Multiple images display variation in color and different aspects of the animals. The quality of the images is generally good, and a significant portion derive from Nepal specimens. As for the Identification section, use of Nepal individuals and samples increases the book's usefulness to those of us who study herps in other parts of Asia. Similarly, I find the habitat and the local consumption-trade images instructive.

The final sections of *A&R of N* include appendices, a bibliography, and indices. I noted earlier the presence of distributional and geographic data in the appendices. The final appendix is a glossary of scientific terms used in the text. The bibliography is extensive, reflecting the broad search of the herpetological literature for information on Nepal amphibians and reptiles. The species or taxonomic index consists of two parts, one arranged as a classification and the second alphabetically. These two include pagination references. The final three indices give Nepali, English, and German vernacular names for the Nepal herpetofauna. Although I am not a strong advocate of vernacular/common names, these indices will be a useful resource for many readers.

An ultimate question must be asked of a book of this size: Is it too large, or rather, did the editors/authors attempt too much? For me, the answer is yes! Multiple, smaller, topically more detailed and focused books would have better served the herpetological and other biological communities. The size of *A&R of N* will prevent most users from taking it into the field. Its cost, while reasonable at 12.5¢ per page, places it out of reach of many biologists and certainly for most Asian ones. Most academic libraries similarly cannot afford to purchase *A&R of N*, so despite its usefulness, its information will be unavailable to the majority of its intended audience. Another fault of attempting to cover all topics in a single volume is that the individual coverage of each topic becomes more superficial, as noted above.

When initially requested to review *A&R of N*, I thought that a comparison with Tej Kumar Shrestha's (2001) recent *Herpetology of Nepal: A Study of Amphibians and Reptiles of Trans-Himalayan Region of Nepal, India, Pakistan and Bhutan* would be useful. Alas, my attempts to find a bookseller who has a copy of the latter have shown that such sellers are as elusive as the yeti. *A&R of N*, in contrast, is readily available. If you have serious interest in the Asian herpetofauna, you should have a copy nearby on your bookshelf.

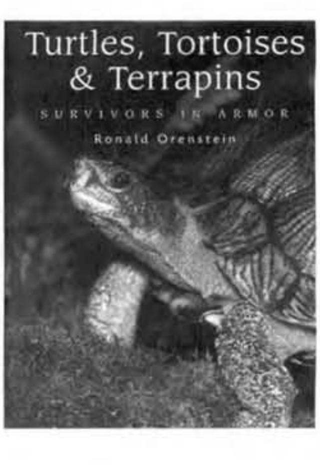
e-mail: william.espenshadeiii@villanova.edu



Chelonians have been treated in many field guides, faunal works, taxonomic monographs, and pet care manuals, but relatively few books in English have considered "turtles for turtle's sake." Some notable exceptions include the popular works by Obst (1986) and Lehrer (1990). Orenstein's comment: "I have written this book because turtles amaze me" is evidence that this is another such book. Indeed, it was written to help

the reader to see chelonians as exceptional and unique animals with specific conservation needs. Although the author is primarily a wildlife conservationist and lobbyist, and not a herpetologist, the combination of his passion for turtles ("I have become not just an admirer of turtles but one of their advocates") and his use of knowledgeable consulting editors (Jeanne Mortimer, George Zug, and Peter Pritchard) has resulted in a well-written and accurate text.

The book begins with "The Essential Turtle," an account of the morphology and physiology of turtles, with a particular focus on the shell and its relationship biological functions, such as respiration. Terms potentially unfamiliar to the novice, such as carapace and endochondral bone, are highlighted in italics and many of the terms and concepts are illustrated by photos. Chapter 2, "Turtles In Time," is a review of both the current thoughts on the evolutionary origins of chelonians as well as the history of these thoughts and how we have come to our current understanding. This chapter is illustrated chiefly by color reconstructions of early chelonians. Charts depicting the temporal relationships of various chelonian ancestors and relatives complement the text. This is followed by two chapters ("Turtles Around the World I & II") presenting an overview of family-level diversity of modern turtles. Familial characteristics are described and illustrated and most genera are mentioned and represented by at least one photo.

Chapters 5–7 cover a diversity of issues in chelonian biology, with an emphasis on terrestrial and freshwater species. "Under the Hood" reviews physiology, with an emphasis on topics such as freeze tolerance, hydration requirements, diving abilities, skin surface gas exchange, and circulatory physiology. "Life as a Turtle" outlines major topics in life history and ecology including life span, intelligence, daily and seasonal activity cycles, orientation, food and feeding specializations, habitat specialization, predators, and ecological roles of turtles. Development, egg output, courtship, sex determination mechanisms, nesting area selection, hatching and hatchlings, and the first season of activity are discussed in "Twixt Plated Decks" (a title derived from Ogden Nashe's poem "The Turtle"). A separate chapter, "The Endless Journey," deals specifically with the biology of sea turtles. The last two chapters of the book, "Peril on Land" and "Peril at Sea" document human-related causes of chelonian declines for freshwater and terrestrial forms and marine species, respectively.

I noted few errors in the text and these were limited chiefly to misplaced words. For example, on page 155: "Since animals cannot digest the cellulose in plants, many *plants* enlist the help of cellulose digesting bacteria." In addition there are a few layout inconsistencies. As a result the second page of the preface ("Why Turtles Matter") bears the header for Chapter 1, "The Essential Turtle." Likewise, the header for the chapter "Peril at Sea" runs into the Bibliography, Index, and Photo Credits sections, where it is either printed above those section's headers or replaces them.

It is clear that the author intended the book to be authoritative and, consequently, the research of many individuals is noted in the text. However, because the book was not intended for a technical audience, there are many cases in which there is no formal citation of the particular publications being referenced. For example, there is no bibliographic entry for a paper by Spotila et al. published in Nature in 2000, which is cited on page 277. In some cases it is not possible to determine if the author or one of the consulting editors is relating a personal observation, referring to unpublished work, or to uncited published works. However, all individuals whose work is cited in the text but not listed in the bibliography appear as entries in the index, along with scientific and common names, place names, other animal and plant names, and key anatomical and biological terms.

Illustrations are essential to the author's goal of generating an appreciation for turtles and their diversity. In all there are 303 color photographs (with an additional five on the dust jacket), 12 color illustrations, five black and white photographs, and three black and white illustrations. Seven range maps present distributions at the family level. All of the photos are of high quality and are well reproduced but many seemingly intended to show the whole animal have a foot, tail, or part of the carapace cropped off. Although no photos are duplicated within the book some Australian turtles can be recognized as the same subject animals figured in John Cann's (1998) *Australian Freshwater Turtles.*

With few exceptions, the animals are correctly identified. However, there are some corrections that should be noted: It appears that on page 19 the photos or text have been reversed, the animal on the left is the common snapping turtle, the animal on the right is the helmeted terrapin. The close-up head photo on page 58 is of a *Phrynops* sp., not the giant arrau, *Podocnemis expansa.* The softshell turtle on page 70 clearly shows septal ridges in the nostrils which would indicate this individual as a spiny softshell, *Apalone spinifera*, not a smooth softshell, *Apalone mutica.* The single basking turtle to the mid left on page 115 is a Florida cooter, *Chrysemys floridana.* The Japanese turtle depicted on page 139 more closely resembles *Geoemyda japonica* than *Mauremys japonica.* The upper right photo in the group of four illustrations on page 179 is a *Trachemys concinna*, not *T. scripta.*

While virtually all the photos show typical "wild type" specimens, those of a Chaco tortoise (p. 107) and a Central Asian tortoise (p. 239) exhibit the uneven shell growth associated with captive care. Although most of the photos clearly illustrate key features of the turtles they depict, two different photos of the pancake tortoise (Chapters 2 and 4) show an animal awkwardly posed in someone's hands and, despite their captions, do not show this species' adaptation to rock crevice occupation.

While *Turtles, Tortoises & Terrapins: Survivors in Armor* is not a technical or reference work by any stretch of the imagination, it would serve as an excellent tool for the basic education of many people for whom an understanding and appreciation of turtles would be beneficial. Among this potential audience are conservation policy makers, state and federal wildlife personnel, and public relations personnel with conservation organizations. Hobbyists seeking more than pet care information will find this book a great addition to their library as will non turtle-oriented herpetologists or animal health care professionals.

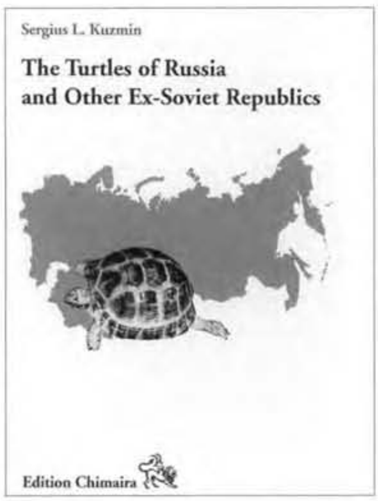
e-mail: Chelonian@aol.com



To characterize the chelonians of the former Soviet Union (FSU) as underrepresented in English language literature would be a gross understatement. A major reason for this is that the massive Eurasian landmass is largely unsuited for this order, yielding low chelonian species richness (Iverson 1992). General works (e.g., Pritchard 1979) have provided some coverage of turtles in the FSU, but these have been largely cursory. In light of the conservation concerns surrounding Asian chelonians, this information-packed octavo volume is particularly welcome and should be considered essential reading for those working with the chelonian species of this area, as well as those with even a passing interest in the subject.

The last significant work in English on the chelonians of the FSU appeared more than 40 years ago and was itself a translation of a much earlier work (Nikol'skii 1915). Although a number of minor works in Russian have been published in the interim, this volume is the first complete modern analysis of turtles of the FSU. Kuzmin is primarily known for his work on amphibians and here he has followed the template of his successful *The Amphibians of the Former Soviet Union* (Kuzmin 1999), bringing a unique perspective to the turtles of this politically and culturally diverse region and integrating his own research with past and present Russian research data previously unavailable in English.

Individual accounts for seven widely distributed species comprise two thirds of the book (105 pages). These provide a wealth of information on morphology, differentiation of subspecies, distribution, habitats, habits, parasites, natural enemies, abundance, activity, reproduction, diet, parasites, physiology, and fossil occurrences. For a book of this size to devote such a considerable amount of space to just seven species is astounding. Nikol'skii (1963) used only 30 pages for the ten chelonians he discussed in a similar area. Most other regional works also offer only a few pages per species (e.g., Das 1991 with 84 pages covering 33 species of the Indian Subcontinent; Lim and Das 1999 with 100 pages covering 25 species in Malaysia). Excluding the marine turtles, which lack wide distribution in this region and account for only nine pages with a combined range map, the individual accounts are generous and comprehensive with page counts ranging from eight (*Mauremys caspica*) to 29 (*Emys orbicularis*).

Sections on morphology, adaptation, and classification are very general in nature, differing little from those found in other, similar works. The balance of the book, however, is quite distinctive. One section deals with the history of chelonian herpetology in the FSU beginning with the work of Peter Simon Pallas in the 18th century. This information complements the author's recent review of the amphibians described by Pallas (Kuzmin 1997). Also of note are introductory sections on ethnozoology and zooarchaeology and the extensive data presented on captive care, anthropogenic pressures, commercial exploitation, and conservation topics.

The simple, but effectively designed pictorial boards appear to be quite sound and durable. The photos of the Russian tortoise on the front and habitat on the reverse are a prelude to the diverse and useful contents. The text layout is clear and organized in a convenient format on glossy paper. It is printed in a small, but readable font with well-reproduced photos, tables, maps, and figures. The 159 pages include three tables and 85 figures, including 76 photographs (67 of which are in color) that illustrate the morphology, coloration, and habitat of the seven species included in the book. Six range maps and several line drawings make up the remaining figures. Two of the three tables deal with egg data while the last identifies chelonian localities in nature reserves of the FSU. The book concludes with a comprehensive bibliography of 161 references, the majority in Russian.

The book could have been improved considerably by a capable English translator or editor. Scarcely a page can be read without encountering English irregularities, beginning with the acknowledgments (p. 6; "I thank…for their informations") and continuing throughout the text (e.g., p. 63; "the animals enter the land and spend many hours basking"). The inclusion of an index would also have greatly increased the serviceability of this work. Despite these relatively minor faults, this is a useful volume for both conservationists and hobbyists. The color photos alone justify the purchase price and shelf space for any chelonian bibliophile or researcher. The clear and concise format and wealth of previously inaccessible data reinforces this opinion. I highly recommend this work as an indispensable treatise for all those interested in turtles and tortoises of the FSU and congratulate Dr. Kuzmin and Chimaira for a timely and well-executed production.

PUBLICATIONS RECEIVED

Non-Erycine Booidea from the Oligocene and Miocene of Europe, by Zbigniew Szyndlar and Jean-Claude Rage. 2003. Institute of Systematics and Evolution of Animals, Polish Academy of Sciences, Kraków, Poland (www.isez.pan.krakow.pl). 109 pp. Softcover. ISBN 83-919407-0-5.

This monograph reviews the fossil booid snakes (with the exception of members of the Erycinae) known from 38 middle Oligicene to middle Miocene (25–7 MY) sites in eight European countries from Portugal to Austria and the Czech Republic. The majority of the material is derived from France and Germany, however, and includes representatives of the Boinae, Tropidophiidae, and Pythoninae. The bulk of the work is devoted to descriptions and systematic accounts, including the descriptions of many new species and a new genus, each illustrated by vertebrae and other skeletal structures. This is followed by an overview of the history of the European Booidea during the period and a consideration of factors leading to the extinction of the non-erycine booids in Europe in the middle Miocene. A literature cited section of more than 150 references completes this thorough treatment of fossil European snakes. This contribution should be of interest to paleoherpetologists as well as snake systematists and those interested in historical biogeography.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.html>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor or Managing Editor.

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR Treasurer (Dr. Theodora Pinou; contact information on inside front cover) or from the SSAR web page (http://www.ssarherps.org/pdf/Adrates.pdf).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Donald Schmitt, SSAR Membership Office, P.O. Box 253, Marceline, Missouri 64658, USA. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below), regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 760	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com.

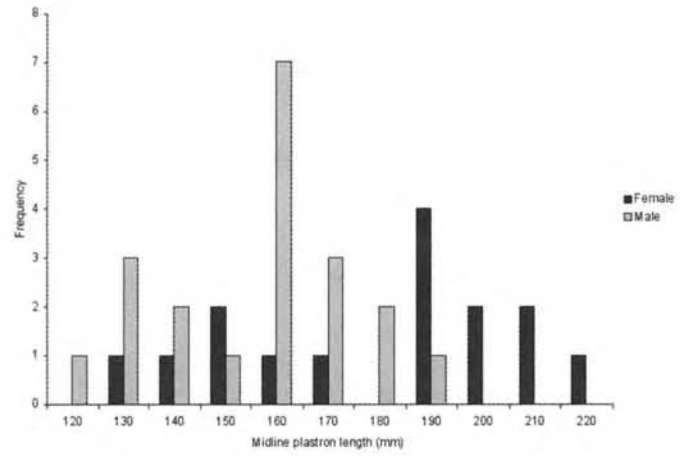

FIG. 1. Size frequency distribution of female and male *T. s. elegans* in Fox Pond.

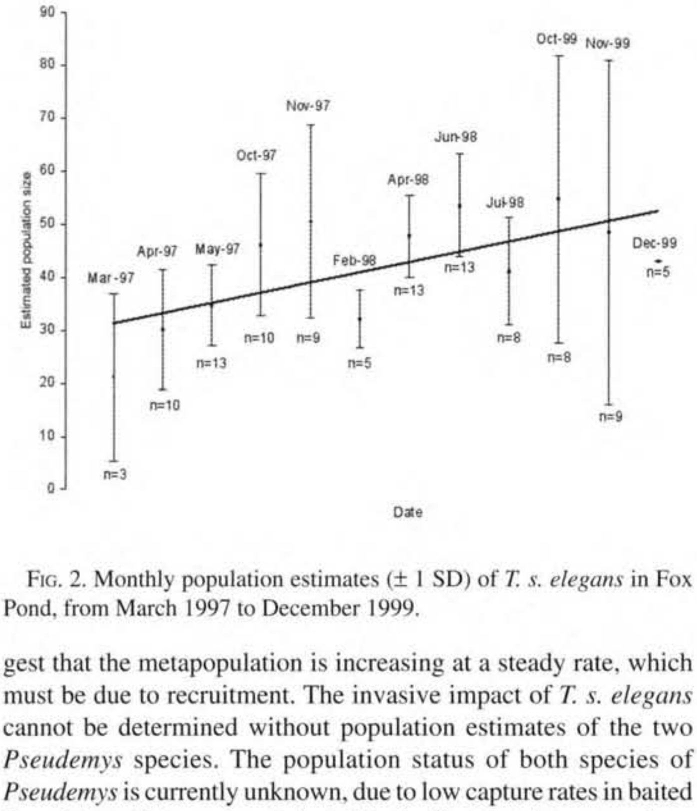

FIG. 2. Monthly population estimates (± 1 SD) of *T. s. elegans* in Fox Pond, from March 1997 to December 1999.

gest that the metapopulation is increasing at a steady rate, which must be due to recruitment. The invasive impact of *T. s. elegans* cannot be determined without population estimates of the two *Pseudemys* species. The population status of both species of *Pseudemys* is currently unknown, due to low capture rates in baited funnel traps that can be attributed to the fact that they are primarily herbivorous.

Acknowledgments—I thank Peter Meylan for his support and guidance throughout this study. Also, thanks to Ecology of Reptiles & Amphibians classes, and the Eckerd Herpetological Society for daily trap monitoring. I thank the Natural Sciences Collegium for their support, and Christopher Boykin and Matt Stone for guidance.

Annual Formation of Growth Marks in a Tropical Amphibian

SURESH M. KUMBAR
and
K. PANCHARATNA*
Department of Zoology, Karnatak University
Dharwad - 580 003, India

**Corresponding author; e-mail: pancharatnak@yahoo.com*

Determining the age of individual animals is extremely important for demographic, population dynamics, or life history studies of amphibians (Castanet and Smirina 1990; Hemelaar and van-Gelder 1980; Kusano et al. 1995; Ryser 1988; Smirina 1994). Mark-release-recapture and skeletochronology are generally used for estimating the age of amphibians (Castanet and Smirina 1990; Hemelaar 1981; Halliday and Verrell 1988; Kusano et al. 1995; Smirina 1994). Counting of growth layers in the phalangeal bones is a non lethal (therefore, ideal for live samples) and a good alternative method for mark-recapture (Coles et al. 2001).

The recent reviews on aging of amphibians reveal that most of the skeletochronological studies on the estimation of age and longevity of amphibians emerge from temperate areas (Castanet and Smirina 1990; Esteban et al. 1996; Halliday and Verrell 1988; Smirina 1994). In these species, the marked seasonality in the ambient temperature is known to result in the formation of distinct annual growth rings consisting in broader growth zones (corresponding to faster bone growth in warmer months) and lines of arrested growth or LAGs (corresponding to arrested bone growth in colder months). Alternately, amphibian species inhabiting constant warmer areas or tropics are expected to express the growth marks inconspicuously or less clearly owing to uninterrupted osteogenesis (Castanet and Smirina 1990; Guarino et al. 1998;

Smirina 1994). However, the limited number of skeletochronological studies available on tropical anurans indicate that the growth marks are expressed in these species as clearly as in temperate species (Barbault et al. 1979; Guarino et al. 1998; Kumbar and Pancharatna 2001ab; Pancharatna et al. 2000). Whether these growth rings are formed annually and can be regarded as year rings for the estimation of age, needs experimental data (Esteban et al. 1996; Guarino et al. 1998; Halliday and Verrell 1988). This study is an attempt to determine whether the growth marks of *Bufo melanostictus* are annual. The common toad *B. melanostictus* inhabiting Dharwad, southern India (where annual variation in mean temperature does not normally exceed 10°C) shows growth marks in the phalanges and long bones of limbs (Kumbar and Pancharatna 2001a). Further, our preliminary studies on the frequency distribution of growth marks in randomly collected toads from natural population reveal that the toads belonging to body mass 8–45 g and SVL 4–7 cm (N = 41) showed no LAGs in phalangeal histology (Fig. 1). Therefore, toads belonging to this body size range were chosen for the present experiment.

Twenty-four young toads with body mass of 10–35 g and snout–vent lengths of 4.5–7.0 cm were collected from the Karnatak University campus, Dharwad (15°17'N, 75°3'E) in the last week of March 1999 (beginning of wet season) and were transported to the laboratory. In the first week of April each toad was anesthetized, body mass and length (SVL) were recorded, and the 4th (longest) toe of the right hind limb was clipped and fixed in 10% formalin and numbered serially. The toads were maintained in the laboratory in a shallow tank (210 x 60 x 30 cm) under room temperature (23.4–28.8°C), similar to ambient temperature (23.6–29.4°C). The laboratory has a glass windowpane through which light entered the room throughout the day (day length varied from 11.05 to 13.11 h). Rainfall in this region occurs principally between April and October and ranged from 15 to 161 mm and 44 and 504 mm in 1999 and 2000, respectively. The animals were fed live grasshoppers every alternate day.

The experiment lasted for one year. Twenty-two toads survived until the termination of the experiment. After one year, in the first week of April 2000, each toad was anesthetized, final body mass and SVL were recorded, and the 4th toe of the left hind limb was clipped and fixed in 10% formalin and numbered serially. All the toads were released at the site of capture. Clipped toes were cleaned and demineralized in 5% nitric acid and processed for paraffin embedding. Sections of 8 μm thick were cut on an ordinary microtome and stained with Harris hematoxylin. Mid-diaphyseal sections were chosen for observation under a compound microscope. Diameter of central medullary cavity (MC), endosteal bone (EB), LAGs and periosteal bone margin (PBM) of right and left phalanx of each toad were measured using an ocular micrometer. The extent of bone growth that occurred and the number of LAGs formed during the experimental period were determined by comparing the measurements of the phalanges clipped initially with those that were clipped one year later. Data were analyzed using Student t-test.

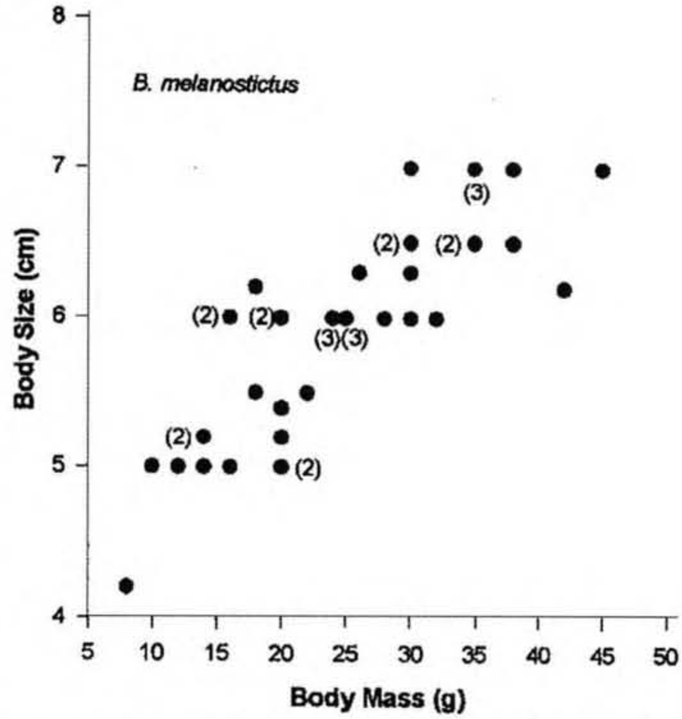

FIG. 1. Relationship between body size (SVL) and body mass (g) of *Bufo melanostictus* which exhibit no LAGs in the phalangeal histology.

At the beginning of the experiment the mean body mass of the toads was 17.2 ± 1.4 g (13 toads weighed between 10 and 15 g; 8 between 16 and 20 g; and 3 between 21 and 35 g), and their SVL ranged between 4.5 and 7 cm with a mean of 5.47 cm (Table 1). The phalangeal histology revealed that in 22 toads, LAGs were completely absent while two toads exhibited one LAG each (Table 1; Fig. 2A). At the end of the experiment, body mass, body length, diameter of MC, EB, PBM, and number of LAGs increased significantly in experimental toads (Table 1). Sixteen toads exhibited 1 LAG and the remaining 6 possessed 2 LAGs each in the cross-section of phalange (Table 1; Fig. 2). In the present study, 18 of 22

TABLE 1. Body mass (g), body size (cm), diameters (μm) of medullary cavity (MC), endosteal bone (EB), LAGs, and periosteal bone margin (PBM) of phalanx of experimental toads obtained at initial and final toe clippings. Values are mean ± $S\bar{x}$.

Toe clipping	Body mass (g)	Body size (cm)	MC	EB	LAG1	LAG2	PBM
Initial (24)	17.17 ± 1.44	5.47 ± 0.16	1039 ± 32	1095 ± 31	1380 ± 180 (2)	—	1588 ± 48
Final (22)	50.15 ± 3.28*	7.03 ± 0.15*	1172 ± 40*	1221 ± 38*	1643 ± 45* (16)	1900 ± 96 (6)	1947 ± 53*

Figures in the parenthesis indicate number of toads. *Significantly ($P < 0.05$) higher compared to corresponding values at initial toe clipping.

toads exhibited an additional LAG (since in two toads the first LAG was already present at the beginning of the experiment and the appearance of a second LAG was expected given the time elapsed). The appearance of a second LAG in the remaining four toads might be explained on the basis that these toads might have been included in the experiment just prior to the expression of first LAG and might have experienced two wet seasons after metamorphosing as adults. LAGs are known to be laid down in tropical species during rainy months (Kumbar and Pancharatna 2001b; Smirina 1994).

Annual formation of LAGs is well established for temperate species such as *Rana temporaria* (Smirina 1972), *Rana esculenta* (Francillon and Castanet 1985), *Bufo bufo* (Hemelaar and van-Gelder 1980), *Triturus cristatus* (Francillon 1980), and *Bufo calamita* (Tejedo et al. 1997). Our study suggests that LAGs are also formed annually in the phalanges of the tropical *Bufo melanostictus*, and therefore could be regarded as annual rings for estimating the age of this anuran.

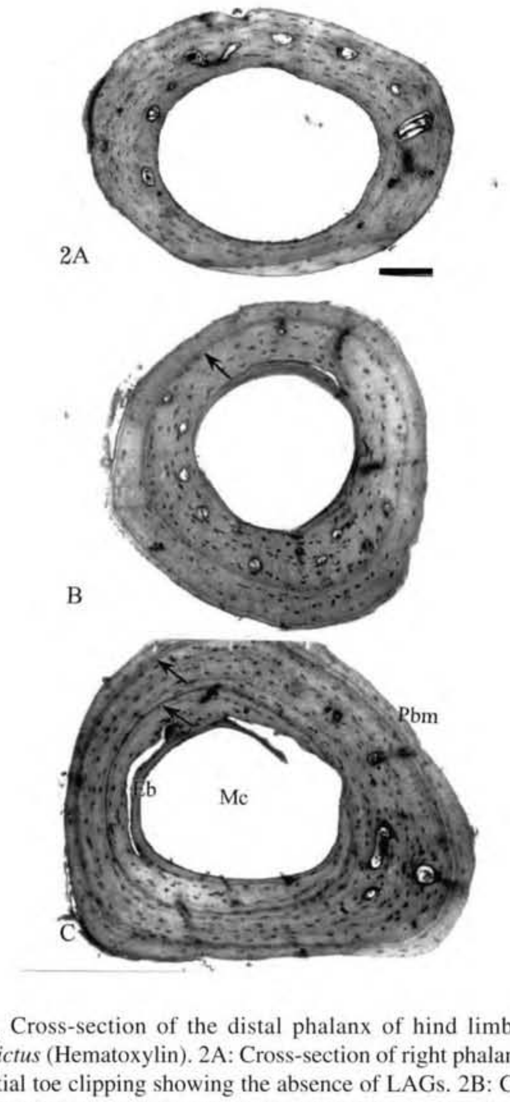

FIG. 2. Cross-section of the distal phalanx of hind limb of *Bufo melanostictus* (Hematoxylin). 2A: Cross-section of right phalanx of toad # 6 at initial toe clipping showing the absence of LAGs. 2B: Cross-section of the left phalanx of the toad # 12 at final toe clipping showing one LAG. 2C: Cross-section of the left phalanx of toad # 17 at final toe clipping showing two LAGs. (MC = medullary cavity, EB = endosteal bone; LAG = line of arrested growth and PBM = periosteal bone margin. Scale line = 100 μm).

Evaluating Elastomer Marking and Photo Identification Methods for Terrestrial Salamanders: Marking Effects and Observer Bias

LARISSA L. BAILEY*
Cooperative Fish and Wildlife Research Unit, Department of Zoology
North Carolina State University, Campus Box 7617
Raleigh, North Carolina 27695-7617, USA

** Present address:*
Patuxent Research Center, 11510 American Holly Drive
Laurel, Maryland 20708, USA
e-mail: lbailey@usgs.gov

Capture-recapture methods are commonly used in ecology and conservation biology to estimate population size and obtain demographic and life-history information on a wide variety of animals. Most capture-recapture methods require individual identification, and assume that: 1) marks are not lost or overlooked by the observer; and 2) there is no mark-induced mortality.

Amphibians are notoriously difficult to mark because of their sensitive skin, small size, and potential for limb and digit regeneration (Murray and Fuller 2000). Nevertheless, a wide variety of marking methods are available including toe-clipping, tattooing, branding, tagging, skin dying or dusting, and subcutaneous dye injection including Visual Implant Elastomer (Northwest Technology Inc., Shaw Island, Washington). Visual Implant Elastomer (VIE) was originally developed for fish, but has recently been used in studies on larval and adult amphibians (Anholt et al. 1998; Davis and Ovaska 2001; Marold 2001; Nauwelaerts et al. 2000). Less-invasive identification methods such as "pattern mapping" or photo identification are possible for some species, but are used less frequently than traditional marking methods (see Gill 1978; Tilley 1980). Few amphibian studies have evaluated marking effects on behavior and survival rates, or tested the additional assumptions of capture-recapture methods (no mark loss or observer bias). Many amphibian marking studies lack control animals, adequate sample sizes, or sufficient study duration to rigorously assess these marking issues (Donnelly 1994; Murray and Fuller 2000). Estimates of observer bias in mark recognition are exceedingly rare (but see Muths et al. 2000).

In a laboratory study, I evaluated the effectiveness of two marking techniques, VIE and photo-identification, to individually identify *Eurycea bislineata wilderae* salamanders. I documented VIE-mark retention, survivorship, and growth rates of marked vs. unmarked salamanders. I also tested observers' ability to correctly identify individuals using: 1) digital photographs of dorsal spot patterns; or 2) VIE marks viewed with two different lights provided by Northwest Technologies. VIE has never been formally tested on any southern Appalachian salamander species and *E. b. wilderae* is a good candidate due to its relatively small size (metamorphosed snout-vent length, SVL = 20–45 mm), dual life history strategy, and broad geographic range (Bruce 1988; Petranka 1998). Furthermore, *E. b. wilderae* has been designated as a Management Indicator Species (MIS) by the U.S. Forest Service for the southern region. As such, populations of *E. b. wilderae* will be monitored to assess the effects of forest management actions.

Materials and Methods.—In June 2001, 53 metamorphosed *E. b. wilderae* (8 sub-adults < 30mm SVL and 45 adults > 30 mm SVL) were collected from Sevier County, Tennessee, outside of Great Smoky Mountains National Park. Salamanders were temporarily stored in refrigerators at 4–5°C and then transported to a temperature-controlled research lab at the North Carolina Museum of Natural Sciences. I recorded the initial weight, length, age (sub-adult or adult), sex, and any abnormalities for each individual. Salamanders were housed individually in 0.71-liter plastic containers on a substrate of damp paper towels. Crumpled damp paper towels were provided as refuge. Each salamander was fed 6–8 small crickets per week and the substrate was replaced weekly. Fluorescent lights maintained a 12:12 L:D photoperiod and the temperature was maintained at 18°C.

Salamanders were allowed to acclimate for two weeks and on 10 July 2001, salamanders were randomly assigned one of two treatments: unmarked but digitally photographed (control, N = 23 individuals) or marked via VIE (N = 24 individuals). Each VIE-marked salamander was subcutaneously injected at 2 of 4 possible locations (anterior to either hind leg or posterior to either front leg) using 1 of 3 colors (red, orange, or yellow). Salamanders were placed individually in clear zip-loc bags and cooled for approximately 5–10 minutes to reduce movement. Salamanders were constrained against the edge of the bag and marks were administered through the bag with 0.3-cc insulin syringe and needles. Needles were cleaned with 95% ethanol between injections.

Every six weeks from June 2001 to September 2002 salamanders were measured and weighed to the nearest 0.01 g using an electronic scale. VIE-marked individuals were examined for mark migration or mark loss using polarized glasses and Northwest Technology viewing lights.

From mid-October to mid-December (ca. 3–5 months after marking), 15 observers were used to assess observer variation for each identification technique. Observers were primarily graduate students with no formal experience with either photographic or VIE marking techniques, but each observer was given a short 5-minute instruction on the VIE-mark identification. I purposely chose observers that were unfamiliar with salamanders and gave them minimal VIE training only. Therefore, results should represent lower limits of proficiency expected from professional biologists and technicians using VIE-marking techniques in field settings.

I tested the effectiveness of two lights manufactured by Northwest Technologies: a dive light with a blue filter lens and a deep blue 7-LED (light emitting diodes) flashlight. Prior to October 2000 the dive light, with halogen bulb, was included in VIE tagging kits, but Close (2000) found that aged VIE marks in fingerling fish were difficult to see when the batteries were not at full strength. Northwest Technologies has replaced the dive lights with the superior LED lights, but because our field studies were conducted using the dive lights (Bailey et al., *in press* a & b), I tested both lights' ability to detect marks in *E. b. wilderae* salamanders.

To mimic field conditions, salamanders were placed in individual plastic bags and viewed with polarized glasses under a rain poncho. We use the poncho in the field to block out ambient light. Each observer viewed 10 randomly chosen marked individuals with one light (randomly assigned), then lights were exchanged, and the 10 animals were re-randomized and presented to the ob-

server again. Observers were unaware that they were viewing the same individuals with both lights. They were not informed of the differences between the two lights, nor were they told how many marks would appear on each salamander. Observers were allowed to have a reference syringe of each color for comparison during the identification process. Data recorded included the marks observed and the time required to identify the marks.

The same 15 observers were used in the photo-identification experiment. Color printouts of the digital, dorsal view photographs were given to observers. The SVL for each individual was written below its picture to provide a size reference. Salamanders were placed in plastic bags and presented to observers who were asked to match the individual with the correct photograph. The time necessary to identify each individual was recorded for each observer.

Repeated measures analysis of variance was used to compare weight gain and growth among marked and unmarked animals. I tested for the main effects of marking, age (sub-adult or adult), sex, and time as well as the interactions of these factors (PROC GLM with repeated statement, SAS Institute 1999). I used a paired t-test to compare the proportion of correctly recognized VIE marks among the two different viewing lights, and a standard t-test to compare the proportion of correctly recognized salamanders between VIE and photo-identification methods. Because all photographed salamanders were presented to each observer, I constructed a capture history matrix for each photographed individual. Correct identification was denoted with a "1" and incorrect identification was given a "0." In this case, observer results are analogous to sampling occasions in traditional capture-recapture situations. Closed-population capture-recapture models were fit using program CAPTURE (Otis et al. 1978; Rexstad and Burnham 1991) and model selection procedures tested the following competing models: 1) no effects model, M_o (equal identification among salamanders and observers); 2) individual heterogeneity, M_h, (variation among salamanders, but not observers); 3) observer effect, M_t, (equal identification among salamanders, but variation among observers); and 4) variation among both salamanders and observers, M_{th}.

Results.—Six salamanders, 3 sub-adults and 3 adults, died during the two-week acclimation period. Following marking, 5 marked and 5 unmarked individuals died and 1 marked animal escaped. Fourteen of these 16 mortalities occurred within the first 6 weeks of captivity, and only 3 of 8 sub-adults survived to the end of the study. Thirty-six of the original 53 salamanders survived to the end of the study. None of the VIE-marks were lost and marks on surviving salamanders could be identified with either the blue filtered dive light or the 7-LED light.

Marked and control salamanders did not differ in their pre-marking weight (t_{45} = -0.85, P = 0.39) or length (t_{45} = -1.12, P = 0.27). Marking had no effect on either weight gain ($F_{1,27}$ < 0.01, P = 0.98) or growth ($F_{1,27}$ = 0.59, P = 0.45) and none of the interactions involving marking effect were significant (using either univariate and multivariate tests). Both weight and length changed over time (P < 0.01). There was a significant time x sex interaction for the weight response variable (Wilk's lambda = 0.42, $F_{9,19}$ = 2.86, P = 0.03, univariate $F_{9,243}$ = 7.24, G-G adjusted P < 0.01, Fig. 1A) and a significant time x age interaction for the length response variable (Wilk's lambda = 0.39, $F_{9,19}$ = 3.29, P = 0.01, univariate $F_{9,243}$ = 3.50, G-G adjusted P = 0.02, Fig. 1B). Females continued to gain weight throughout the study, but males stopped gaining weight after January 2002 (Fig. 1A).

Mark recognition by observers was high for all identification methods, especially photo-identification (Fig. 2). The type of light did not affect an observer's ability to correctly identify VIE-marked individuals (t_{14} = -0.69, P = 0.50), nor was there a difference between photo-identification and the currently marketed 7-LED light (t_{14} = -1.8, P = 0.08). Observers misidentified VIE-marked individuals on 39 of 300 identification opportunities (10 salamanders x 2 lights x 15 observers). Observers had difficulty finding marks on 3 marked salamanders resulting in 15 misidentifications. One salamander accounted for 10 of 15 missed marks, because one of its marks was quite small. The remaining mistakes consisted of color misidentification (21 occasions) and incorrect mark locations (3 occasions). Observer performance was better using photo-identification where salamanders were misidentified on only 16 of 270 possible occasions (18 salamanders x 15 observers). All observers correctly identified 7 salamanders, 7 salamanders were misidentified once, 3 were misidentified twice, and 1 was misidentified 3 times. Model selection procedure in program CAPTURE suggested that there was variation among observers and individuals (models M_t and M_{th} were equally likely). The proportion of salamanders correctly identified by observers ranged between 0.67–1.00 (mean = 0.94 ± 0.02, N =15 observers).

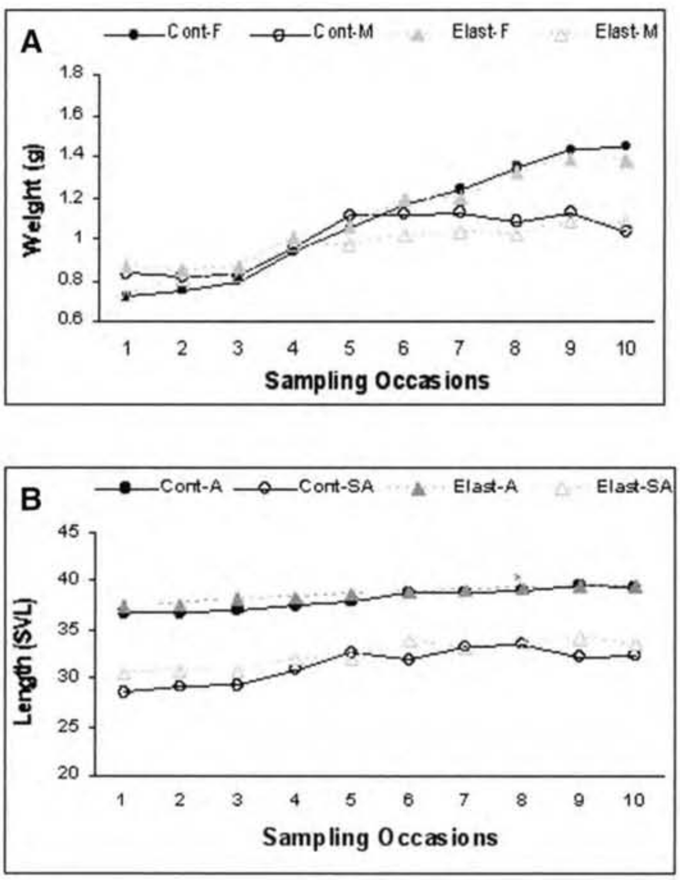

FIG. 1. Average weight (g) of male and female salamanders (A) and average snout-vent length (mm) of adult and sub-adult salamanders (B) sampled at 6-week intervals from July 2001 – May 2002. Cont = Control salamanders; Elast = salamanders injected with elastomer; M = Male; F = Female; A = Adult; SA = Subadult.

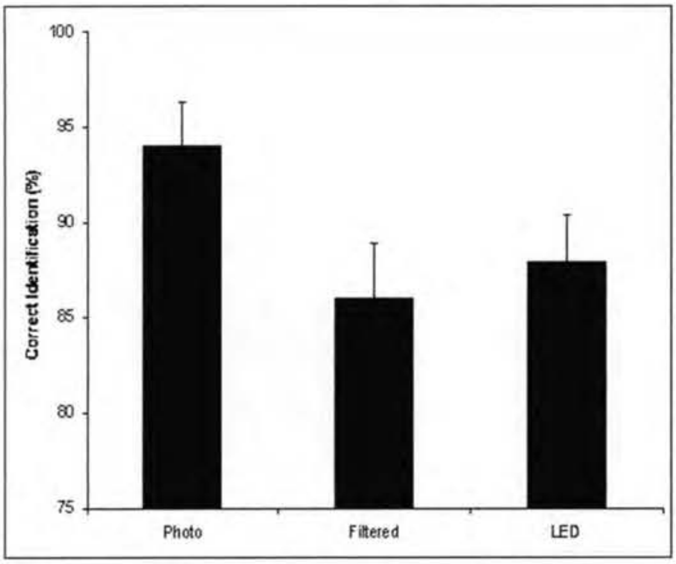

FIG. 2. Average percent of salamanders correctly identified by observers using 3 different methods: photo-identification, VIE-marks viewed with blue filtered dive light, and VIE-marks viewed with deep blue 7-LED light. N = 15 observers.

Observers were able to identify individuals using VIE-marks more quickly than by matching individuals to photographs (VIE mean [sec] = 18.0 ± 0.75, N = 298 identification attempts; Photo mean [sec] = 55.0 ± 3.15, N = 270 identification attempts). Some observers spent over 5 minutes matching individual salamanders to photographs.

Discussion.—Both VIE-marking and photo-identification methods were able to individually identify salamanders and met the critical assumptions necessary for capture-recapture studies. There was 100% VIE-mark retention over 11 months with little mark migration or mark reduction. Only 1 of 18 marked salamanders had a small mark that was consistently missed by observers. VIE marking had no effect on *E. b. wilderae* growth or weight gain, adding to similar findings from studies on western red-backed salamanders, *Plethodon vehiculum* (Davis and Ovaska 2001), and larvae of *Rana* species (Anholt et al. 1998). Marking did not inhibit reproductive development; most of our female salamanders developed eggs during the spring months. Presumably the significant time x sex interaction in the weight response variable was due to egg development. Mortality early in the study may have resulted from stress associated with handling or feeding prey that were too large for the smaller individuals.

There were no differences in observer's ability to detect specific VIE-colors, but observers needed practice to correctly identify the colors. Observers commonly commented that the polarized glasses and viewing lights were necessary to see the VIE-marks, but that the colors looked different when viewed with the lights: red VIE looked orange, orange VIE looked yellow, and yellow VIE looked green. Despite having reference syringes, color misidentification was the most common mistake among VIE-marked individuals (21/39 = 54% VIE misidentifications). When we mark salamanders in the field, the marks are always checked before the salamanders are released, thus new workers are exposed to hundreds of known color marks before they are required to read an unknown VIE-marked individual. This study purposely included minimal observer preparation, and the results represent a lower bound of observer proficiency. The results show that observers with little training can correctly identify about 85% of marked salamanders, and therefore field recognition rates with trained observers are likely much higher.

Photo-identification may be an underutilized identification technique in salamander studies. This technique was used in early salamander studies (Forester 1977; Gill 1978; Tilley 1980), but more recently it has only been used to verify other marking methods (Davis and Ovaska 2001). Advances in camera and computer technologies combined with good observer performance should encourage the use of photo-identification as a primary identification method for species with distinctive marking patterns. Photo-identification would presumably be much more difficult and less accurate with larger numbers of individuals without computer aided matching techniques. Furthermore, photograph quality has been shown to affect matching likelihood (Kelly 2001; Whitehead 1990). Observers in my study commented that picture clarity was good, but glare from the camera's flash and salamander positioning sometimes inhibited identification. It is important to note that observers in my study were not presented unmarked individuals for either marking technique (i.e., unmarked or non-photographed individuals). This is unlikely to affect VIE identification rates, but correct photo-identification rates may have been reduced if unphotographed individuals were also presented to observers. Finally, future studies that explore potential changes in spot patterns over time are still needed (Reaser 1995).

Individual marking or identification methods are rarely tested with adequate controls, sample sizes, or duration. We hope this study design serves as an example of steps that can be explored to assure capture-recapture assumptions are met, regardless of the identification method. This study contributes to the growing body of literature that supports using VIE-marking methods in terrestrial amphibian and reptile species. Future studies that focus on the retention of elastomer marks from larval to adult states would be extremely beneficial for long-term studies of pond and stream-breeding amphibians. Photo-identification also shows good potential as a non-invasive identification technique, especially if samples sizes are small or if computer-aided matching becomes available. Investigators could combine the two techniques in a double-marking format to test for VIE mark retention in field studies.

Acknowledgements.—The North Carolina Herpetological Society provided funding for this research. I thank Ed Malindzak and the staff of North Carolina Museum of Natural Sciences, especially A. Braswell, D. Davenport, and L. Albert for their logistic and administrative assistance. J. Godwin, N. Haddad, K. Pollock, T. Simons, D. Olson, and three anonymous reviewers provided valuable suggestions to an earlier draft of the manuscript. Finally, I would like to thank all the observers for donating their time.

Biology of the Rattlesnakes Conference

A conference on "Biology of the Rattlesnakes" will be held 16–18 January 2005 at the Wong Kerlee International Conference Center, Loma Linda, California, USA. Conference topics will include systematics, behavior, natural history, snakebite/toxicology, conservation/management, and research techniques relating to rattlesnakes. A peer-reviewed reference volume is planned, based on presentations at the conference. The conference will be hosted by Loma Linda University's Department of Natural Sciences and Loma Linda University Medical Center. Details can be found at <http://www.BiologyoftheRattlesnakes.org>.

Fish and Company Smell After Three Days: Increasing Capture Rates of Carrion-Eating Varanid Lizards

JAMES SMITH
Key Centre For Tropical Wildlife Management, Northern Territory University
Northern Territory, Australia, 0909
e-mail: james.smith@ntu.edu.au

Fourteen of Australia's 44 varanid species are found in the tropical north (Cogger 2000) and are some of the most common and conspicuous predators in tropical ecosystems. Despite this, there is little information on the basic biology of many of these species. One of the factors that may be hindering such studies is the difficulty in obtaining large numbers of specimens from the field.

I describe here a passive trap design devised to increase capture rates of the mangrove monitor *Varanus indicus*, a species whose Australian distribution is restricted to coastal and estuarine mangrove forests of the Northern Territory and Cape York in Queensland (Cogger 2000). In suitable habitat, *V. indicus* can be quite abundant but difficult to sight and even more difficult to capture, because of their effective camouflage and a tendency to climb high into trees (sometimes 10 m or more) when alarmed (pers. obs.). To overcome this problem, a new pipe trap has been developed, providing a simple, sturdy and portable design, suitable for even the most difficult environments.

Many methods have been used to capture free-living monitors. Large monitor species that can be easily approached can be noosed (*Varanus mertensi, V. gouldii*, J. Koenig, pers. comm.) although this method can result in injury to the animal (pers. obs.). Monitors can also be dug from or trapped outside their burrows (e.g., *V. gouldii*, King 1980) but this method is somewhat labor-intensive and destructive to habitats. Some species (*V. tristis*) have been caught by following their tracks in the sand to their resting sites (Thompson et al. 1999). However, for large, wide-ranging species and those using habitats where it is difficult for humans to move about freely, conventional active capture techniques cannot be employed.

Passive capture methods have proved effective for some varanid species. Pitfall traps have been used to capture *Varanus brevicauda, V. eremius, V. gilleni, V. gouldii,* and *V. tristis* (Downey and Dickman 1993). Passive nooses (set in likely travel corridors) have been used for the elusive rock-dwelling species *V. glebopalma* and *V. glauerti* (Sweet 1999). While effective, these methods require constant monitoring (three times daily), a task unachievable over large areas, and are unsuitable in tidal environments such as mangrove systems.

To circumvent the problems posed by tides, Auliya and Erdelen (1999), after experimenting with many methods, devised a floating carrion trap (box trap) to capture the large water monitor *Varanus salvator*. These traps were baited with fish or chicken viscera and relied on a monitor entering the trap, grabbing the bait and triggering a mechanism to close the door behind it. Although effective, these traps were large, were erected on site and took 5–7 days to construct using local materials (bamboo and wood). Erecting large numbers of traps of this type is likely to prove prohibi-

tively expensive. In north Australian estuarine environments, the estuarine crocodile (*Crocodylus porosus*) may be attracted to and possibly interfere with carrion traps, as well as posing a risk to field workers.

To overcome the weaknesses of these previous designs, I devised a baited arboreal pipe trap. The traps were made from 1 m lengths of PVC stormwater pipe, sealed at one end with PVC push-on end caps. Traps are placed vertically with the sealed end at the bottom and rely on gravity and the smooth sides of the pipe to prevent escape of varanids entering them. Traps could be made with practically any diameter, depending on the size of the target species. To allow drainage of water after heavy rains and facilitate spread of bait odors, three 6 mm holes were drilled through the end caps and three near the base (ca. 100 mm from the end cap) at equal intervals around the pipe. The lip of each trap was filed smooth to remove the sometimes sharp edges created when cutting from a larger length of pipe. Depending on the availability of materials (new vs. secondhand pipe, etc.), these traps were quite inexpensive to produce.

Traps were strapped vertically on trees using 10 cm wide adhesive tape. Attachment was quick and the trap and animals readily removed by simply cutting the tape with a sharp knife. Brightly colored tape was used to increase the visibility of traps when searching for them in dense forest. If the traps were placed high enough in trees they could be left set, undisturbed by the raised water levels caused by tidal or seasonal influences. However, low-set traps present no risks to these semi-aquatic animals because they are able to escape the trap as water levels rise. High set traps were checked once each day with a small hand held mirror, used to peer into the entrance.

To test the effectiveness of the design, twelve pipe traps of two different diameters were used (six 150 mm and six 225 mm). These were set within a 2 ha patch of estuarine mangrove forest on the Adelaide River, 70 km E of Darwin. Trapping took place over six consecutive days in early August 2001. Traps were baited with a small amount of meat or fish and placed vertically on the main trunk of mature mangrove trees (predominantly *Avicennia marina*, *Sonneratia lanceolata* and *Xylocarpus mekongensis*).

Pipe traps of both sizes were found to be highly effective for this species, with an overall trap success rate of 50% (36 captures in 72 trap days). Daily trap success rates (from 12 traps) ranged from 8% (1 capture) to 75% (9 captures). These results compare very favorably with previous hand-noosing results for *V. indicus* from the same area, which on average yielded less than one successful capture per day. Traps were found to be safe, with no trap mortality and no obvious trap-related injuries. No trapped animals appeared to be agitated or exhausted on removal and release.

The effectiveness of these traps appears to be related to the pungency of baits used, as strong-smelling baits (rotting fish) tended to catch more individuals (Fig. 1). Traps set with less "smelly" food items (pork or lamb cuts, or recently bought fish) caught no animals. Animals were captured more frequently when fish had been in the traps for extended periods (i.e., once it had begun to decompose). Recaptures occurred both at the same trap and at different trap locations. On two occasions two animals were captured in the same trap.

As many other Australian varanids are attracted to carrion (*Varanus gouldii*, *V. panoptes*, *V. rosenbergii*; King and Green 1999;

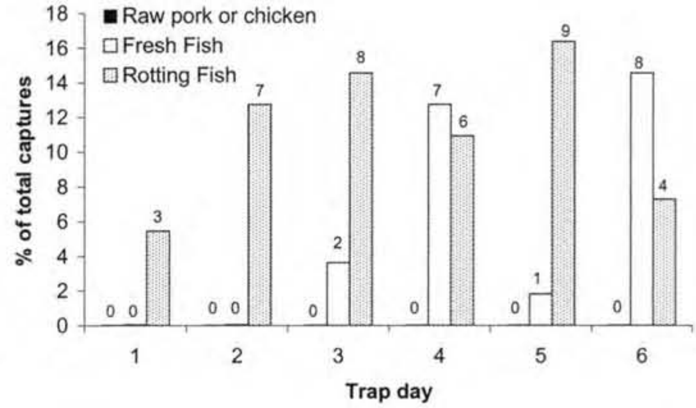

FIG. 1. Number of captures of *Varanus indicus* using different baits in pipe traps (12 traps, 6 trap days per session). Numbers above bars indicate actual numbers caught. Baits were retained unchanged for the 6-day sampling period. Raw pork or chicken caught no *V. indicus*.

pers. obs.), these traps may prove to be useful in other habitats where conventional methods cannot be applied. Care should be taken, however, to use the appropriate attractants. Decomposing fish was found to be most effective for this study, possibly due to the rancid odors that can be produced from small quantities of fish (Richards and Hultin 2001). While this trial used arboreal placement, the pipe trap design can readily be adapted for use in rocky environments or even in-ground use when matched with an auger of appropriate diameter. As in this study, consideration must always be given to the welfare of captured animals, to ensure that trapping does not expose them to risks of drowning, suffocation, temperature extremes or predation (particularly by insects). This may be done simply by appropriate trap placement, but in some circumstances other refinements will be necessary such as ant barriers, or rain hoods.

In conclusion, this new pipe trap design has provided an effective, yet affordable method for increasing capture rates of *V. indicus* and thereby enhancing research on this little-studied and secretive species. Baited pipe traps may also prove to be of similar utility in the capture of other carrion-eating varanids, allowing the establishment of highly informative mark-recapture survey and monitoring programs.

Long-term data typically are collected by different people under varying field conditions, resulting in data sets that are difficult to standardize. Several researchers have examined this problem in varied taxa, such as birds (Arendt and Faaborg 1989; Grant 1979; Yezerinac et al. 1992; Zink 1983), bats (Palmeirim 1998), and snails (Bailey and Byrnes 1990). However, they have used museum specimens or shells. Data for live animals are even more difficult to standardize. The most common data collected on crocodilians are morphometric measurements (e.g., head length, snout–vent length, total length, and mass). These measurements are used in a wide range of analyses, from ecological to taxonomic to evolutionary (Chabreck and Joanen 1979; Hall 1991; Hutton 1986). However, these analyses are only as accurate as the data from which they are derived.

We performed morphometric measurement trials on the American alligator, *Alligator mississippiensis*, to quantify inter-measurer error and determine which morphometric measurement had the least measurer error associated with it. This is necessary to increase confidence levels in future analyses.

Two trials were performed: 1) measurers were inexperienced volunteers; 2) measurers were experienced alligator biologists. The inexperienced trial was performed in the fall of 2000 using ten alligators captured at Arthur R. Marshall Loxahatchee National Wildlife Refuge (Loxahatchee) located in Boynton Beach, Florida (USA), with six groups of volunteers. Alligators were located by observing eye shines from an airboat in the marsh interior and captured using a wire snare. Alligators were secured in the boat and brought back to a covered area for measurement. Alligator size varied from 108 to 248 cm total length. The volunteers consisted of Loxahatchee staff, University of Florida employees, U.S. Geological Survey employees, and students from Palm Beach Atlantic Community College. Each group consisted of 4–6 people who were given both verbal and written measurement instructions. Each group measured every alligator. Different individuals within the group took measurements of each alligator, but measurements were agreed upon within the group before being recorded. Participants were allowed to collaborate within but not between groups. The following were measured by each group on every alligator: head length (HL), snout–vent length (SVL), total length (TL), right hind foot length (HFL), neck girth (NG), tail girth (TG), chest girth (CG), and mass. HL was measured dorsally, while SVL and TL were measured ventrally. A measurement kit was provided with every alligator that contained the following: a clipboard, pencil, string for measuring tail girth between scutes, a Pesola scale, and a flexible centimeter sewing tape. These kits stayed with the alligator so that the same equipment was used. Measurements were made with the flexible sewing tape to the nearest 0.1 cm. Mass was measured with 10–50 kg Pesola scales to the nearest 0.1 kg. The scales were calibrated before use using a weight of known mass. Before release, alligators were marked with individually numbered size 3 Monel tags in the webbing of the back left foot, and scute clipped for permanent identification.

The second trial was performed in fall 2001 with experienced alligator biologists. Nine alligators ranging from 156 to 255 cm TL were captured at Loxahatchee and used for the trial. Ten biologists measured each alligator using the same procedures and instructions as in the previous experiment with three exceptions: 1) each individual measured every alligator and was not allowed to discuss their findings; 2) the participants worked in groups of two to facilitate measuring; and 3) each person recorded their own measurements to reduce bias in and among groups.

Data were analyzed to determine which measurements were most reliable, or contained the least percent measurement error (%ME). Differences in reliability between experienced and inexperienced groups were evaluated using coefficient of variation. Standard deviation for each measurement was calculated and divided by the mean of that measurement for that alligator. A T-test was performed on the coefficients of variation to compare the reliability of experienced and inexperienced measurers. Six of the experienced measurers were randomly chosen so that the N in the T-test would be equal to the six groups of inexperienced volunteers.

The results of the T-test (Table 1) suggest that experienced indi-

TABLE 1. T-test results for coefficient of variation of experienced individuals versus inexperienced groups of volunteers. * Denotes significant value ($p < 0.05$).

Measurement	P-value
HL	0.046*
SVL	0.098
TL	0.129
HFL	0.758
CG	0.010*
NG	0.284
TG	0.015*
Mass	0.010*

viduals measure more accurately for HL, CG, TG, and mass than groups of inexperienced volunteers. There is no statistical difference for SVL, TL, HFL, and NG.

Percent measurement error was calculated for the experienced group to determine which measurements are more reliable for morphometric studies. Bailey and Byrnes (1990) pioneered the use of Model II ANOVA and ANCOVA to estimate within-individual and among-individual components of covariance and variance to predict percent measurement error. A Model II ANOVA and ANCOVA was run as a part of the SAS NESTED procedure (SAS Institute, Inc. 1988), according to the Bailey and Byrnes (1990) procedure. The among-individual variance was calculated by the following equation (Yezerinac et al. 1992):

$$s^2_{among} = (MS_{among} - MS_{within}) / m,$$

where MS is the mean squared deviation and m is the number of repeated measurements. Covariances were calculated as follows:

$$r_{x.y\ among} = (cov_{x.y\ among} / sx_{among}\ sy_{among}).$$

%ME was then determined by:

$$\%ME = 100\%\ (s^2_{within} / s^2_{within} + s^2_{among}).$$

TABLE 2. Within alligator variance and covariance components for length and volumetric measures. Diagonal elements are variance components represented by percent measurement error (%ME). The off-diagonal elements are covariance components represented by within-gator correlations (rwithin).

	HL	SVL	TL	HFL	NG	CG	TG	Mass
HL	0.79							
SVL	-0.07	1.52						
TL	0.02	0.01	3.88					
HFL	0.09	-0.15	0.01	49.53				
NG	-0.04	0.16	-0.15	0.14	7.64			
CG	-0.03	0.10	0.16	-0.22	0.31	4.89		
TG	-0.06	0.09	0.10	0.10	0.63	0.40	2.93	
Mass	-0.08	-0.08	0.09	0.04	-0.25	-0.10	-0.13	0.50

Percent measurement error ranged from 0.50 to 49.53% (Table 2). HFL had the highest %ME because the landmarks used for the measurement are not easily located. TL was also relatively high. TL should be one of the most reliable measurements, as it is the largest and allows for greater margin of error. It is interesting to note the high covariance that NG and CG share with the other volumetric measurements.

This assessment can be used as a guide for future crocodilian studies that use morphometric measurements, such as the analysis of growth rate and condition. If performing morphometric analysis using data obtained by inexperienced groups, it would be more accurate to use TL, SVL, or NG. For experienced individuals, HL, SVL, TG, or mass should be used. For example, condition factor analysis requires a skeletal measurement and a volumetric measurement. SVL would be adequate for the skeletal measurement regardless of who collected the data, but more care should be taken in choosing the volumetric measurement. If these trials were to be replicated, it would be useful to modify the design so that each individual would take three or more measurements of each measurement for each alligator. This would provide data to quantify intra-observer error.

Use of Artificial Egg Laying Substrate to Detect California Tiger Salamanders (*Ambystoma californiense*)

JEFF A. ALVAREZ
The Wildlife Project, P.O. Box 579805
Modesto, California 95357, USA
e-mail: azoologist@sbcglobal.net

Many techniques have been used when surveying for the presence of California tiger salamanders (*Ambystoma californiense*) and other amphibians. Night spot-lighting, dip nets, seines, cast nets, drift fences, pit-fall traps, cover boards, and visual and auditory observations have all been used to determine amphibian presence (Bean 1999; Brode 1997; Corben and Fellers 2001; Fellers and Freel 1995; Heyer et al. 1994; Langton 1989; pers. obs.). In 1997 a protocol was developed by the California Department of Fish and Game to survey for the California tiger salamander (Brode 1997). The protocol recommended using land transects for adults, and aquatic larval surveys using dip nets and seines. In 1999 an addition was made to the protocol, which included the use of minnow traps to detect larvae (Bean 1999). The minnow traps facilitated the detection of larvae in deep or heavily vegetated ponds and wetlands.

Although many amphibians demonstrate species-specific preferences with respect to oviposition sites (Beebee 1997), *A. californiense* may deposit its eggs on stones, twigs, submergent and emergent vegetation, and other debris on the bottom of ponds or wetlands (Stebbins 2003). This behavior offers the opportunity to supply artificial oviposition sites that can then be used to detect the presence of this salamander. Recommended here is a technique that allows for detection of *A. californiense* without risk of mortality to salamanders and other amphibian larvae, and with a great reduction in time expended.

A grid was constructed from 13-mm (1/2 inch) polyvinyl chloride (PVC) tubing and 3-mm (1/8 inch) nylon cord. Tubing was cut into two 1-m lengths and two 0.5-m lengths and joined together in a rectangular shape with PVC glue and fittings (Fig. 1.). Around the perimeter of the rectangle, 6-mm (1/4 inch) holes were drilled at intervals of 10 cm. The nylon cord was drawn through the holes, woven over and under one another, and tied at the ends to keep the cord in place. A 45-cm (18 inch) length of foam pipe insulation (used by plumbers to prevent 1/2 inch pipe from freezing) was glued around one of the shorter lengths of the grid tubing.

Egg grids were placed in perennial and ephemeral ponds prior to and during the breeding period for *A. californiense*. Typically the grid was placed within 2 m of the shoreline and secured to a small wooden stake with a length of nylon cord. One end of the grid floated while the other end sank toward the bottom (Fig. 2.). Grids were checked every 7–10 days and eggs were identified and counted.

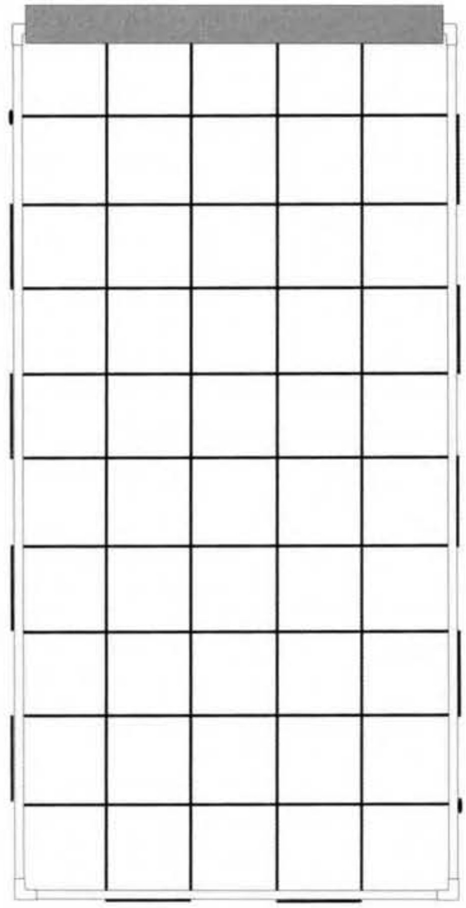

FIG. 1. Rectangular PVC egg grid with nylon cord alternately woven as shown. Foam insulation attached to the upper portion provides flotation.

At the Los Vaqueros Watershed, Contra Costa County, California, visual surveys, minnow traps, seines, and dip nets were used to determine the presence of *A. californiense* in (up to) 90 perennial and ephemeral ponds. Surveys for the presence of *A. californiense* were made during six different years between 1989 and 1999. Within those years, the number of ponds that were reported to have *A. californiense* ranged from 2 to 30 (average = 13.8 ponds). During the winter of 2000–2001, the same ponds were surveyed using egg grids and the presence of *A. californiense* was observed in 69 of 90 perennial and ephemeral ponds. Eggs

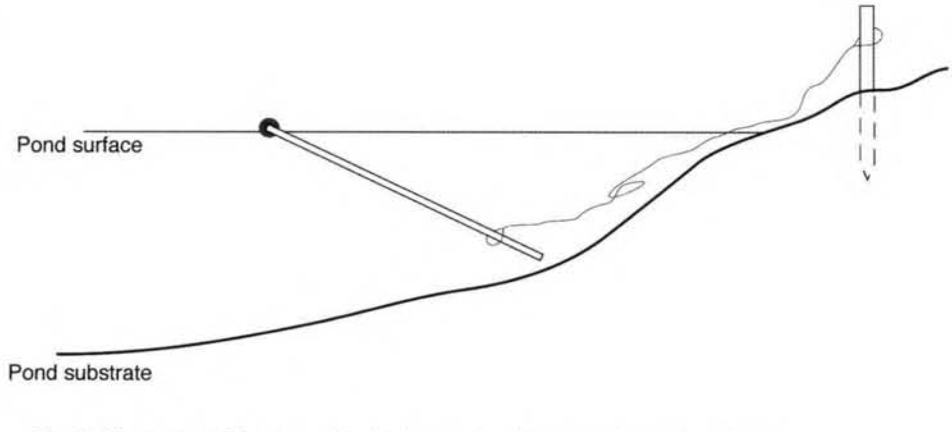

FIG. 2. Placement of the egg grid within a pond with an attachment to a stake.

were present on grids from mid-November through late-February. Presence of eggs on the egg grid was the sole or primary source of identification in 49 of the 69 ponds. Egg identification confirmation was made by the examination of larvae later in the season.

A note of caution: considerable care should be taken when examining habitat within the range of the introduced tiger salamander (*A. tigrinum*; Bean 1999). Under these circumstances neither eggs nor larvae should be used for species identification. Genetic testing should be used to discriminate between these species.

The addition of this technique to the survey protocol may increase detection of *A. californiense*, particularly in turbid water bodies. Additionally, it can reduce or eliminate the need for Federal 10(a)(1)(A) permit for take of California red-legged frog (*Rana aurora draytonii*) larvae that are sympatric with *A. californiense*. Further, many ponds can be surveyed simultaneously with relatively little time expended and a marked reduction in potential mortality.

Acknowledgments.—I thank W. K. Weber for her contributions to the design of the egg grids and for her helpful comments on the manuscript; M. van Hattem for his insightful observation and comments; and J. L. Alvarez for her helpful comments on the manuscript. I thank the Contra Costa Water District for support.

The reproductive biology of the brown treesnake (*Boiga irregularis*), an invasive tropical species known primarily for the extensive ecological damage it has caused on the island of Guam (Savidge 1987), is poorly understood. This is not for lack of sampling effort by researchers—it is simply because reproduction apparently occurs in all months of the year (Rodda et al. 1999) and periodic sampling in such systems cannot detect the phenology of major reproductive events (e.g., ovarian recrudescence, ovulation, oviposition) and other important life history attributes (e.g., frequency of reproduction). In such systems, repeated observations of individuals may be the only recourse for obtaining such information. Accordingly, we recently established a captive colony of brown treesnakes at our facilities and were able to successfully induce reproduction in a number of females (Mathies and Miller 2003). Here, in our second effort to induce reproduction in this colony, we report on the phenology of ovarian recrudescence, the conditions that initiate this process, and the possibility that copulation may be necessary to induce ovulation.

Details on origin, husbandry, and procedures for mating of the snakes in this study are the same, or similar, to those given in Mathies and Miller (2003). Snakes in our colony (10 males, 15 females) were collected as adults on Guam and are the same individuals used in a previous breeding study (Mathies and Miller 2003). Because of space limitations, snakes were housed in two adjacent rooms. Temperatures in the rooms were thermostatically controlled and no other heat sources were available to snakes. Differences in air temperatures between the two rooms were unintended and due to equipment malfunction (Fig. 1). Overall mean temperatures during the study period, however, were similar (Room A: 22.8°C; Room B: 22.9°C). Relative humidity in both rooms was maintained at about 80%. Room lighting was provided by fluorescent bulbs and the photoperiod was 12L:12D. The time of year this study was conducted was chosen out of convenience. Dates provided herein should not necessarily be taken to imply that the brown treesnake is more likely to become reproductive at

this time of year than any other.

Mating trials were conducted by placing a female in the cage of a male and then observing the pair for at least 30 minutes for courtship behaviors. Trials were conducted in near darkness and pairs were observed using Sony CCD-TRV58 video cameras equipped with infrared light emitters (Sony Electronics Inc., New Jersey, USA.). Trials were conducted at approximately 14-day intervals beginning on 7 November 2001 and ending on 3 March 2002. Each female was placed with a male once during each group of trials and with a different male each time. In the majority of trials, males showed little or no interest in females. Males performed dorsal advances followed by tail searching behavior in only four trials with no one male or female participating more than once. These four trials were distributed fairly evenly throughout the period of mating trials. There were no successful intromissions. We assume the males were in adequate reproductive condition because these same males were highly attracted to females when kept under similar environmental conditions to those used here (Mathies and Miller 2003).

Females were palpated for the presence of enlarged ovarian follicles on one to two occasions within 30-day intervals beginning on 8 January 2002 and ending on 3 July 2002. The method for palpating females was quick and relatively unobtrusive; it simply involved lifting an individual from its cage and then feeling for follicles as it crawled back into its cage. We were first able to detect enlarged follicles in a few females approximately three months after the end of the cool period (Fig. 1). Within two weeks of that examination, all eight females in Room A had enlarged follicles and six of the seven females in Room B had enlarged follicles. At this time all such females contained follicles judged to be at least 30 mm in length, which is about the size of brown treesnake eggs (Mathies and Miller 2003; Rodda et al 1999). Thus, follicles were presumably at, or close to, ovulatory size. The number of follicles per female was not related to female body mass (Linear regression: $R^2 = 0.08$, $P = 0.35$), which was somewhat unexpected, but we did not measure snout–vent length, which is generally a better predictor of reproductive investment. There was no difference between rooms in the number of follicles per female (Mann-Whitney U-test: $P = 0.85$, $U = 22.50$). The modal (and maximum) number of follicles per female was nine. The frequency of females with respect to their follicle count is shown in Fig. 2. The numbers of follicles per female we observed are in line with clutch sizes reported for females from the Guam population (Mathies and Miller 2003; Rodda et al 1999) suggesting that these numbers are translatable to clutch sizes. The first examination where we noted females with either no palpable follicles, or flaccid-feeling follicles, occurred approximately two months from the date follicles were first detected. At about 12 weeks past the date follicles were first detected, no females had palpable follicles. That is, all follicles had apparently become atretic and had been, or were being, resorbed. The timing and durations of the events reported above would have been temperature dependent, thus, we do not know how representative they are of those on Guam.

The cue that initiates ovarian recrudescence in the brown treesnake has not been specifically identified. In the present, as well as a previous study (Mathies and Miller 2003), follicles became enlarged following a period of cool temperatures. However, in both studies, females were placed together with males following the cool periods and thus we cannot rule out the possibility that contact with a male was the cue. Studies on female red-sided garter snakes revealed that in some years, at least, copulation ini-

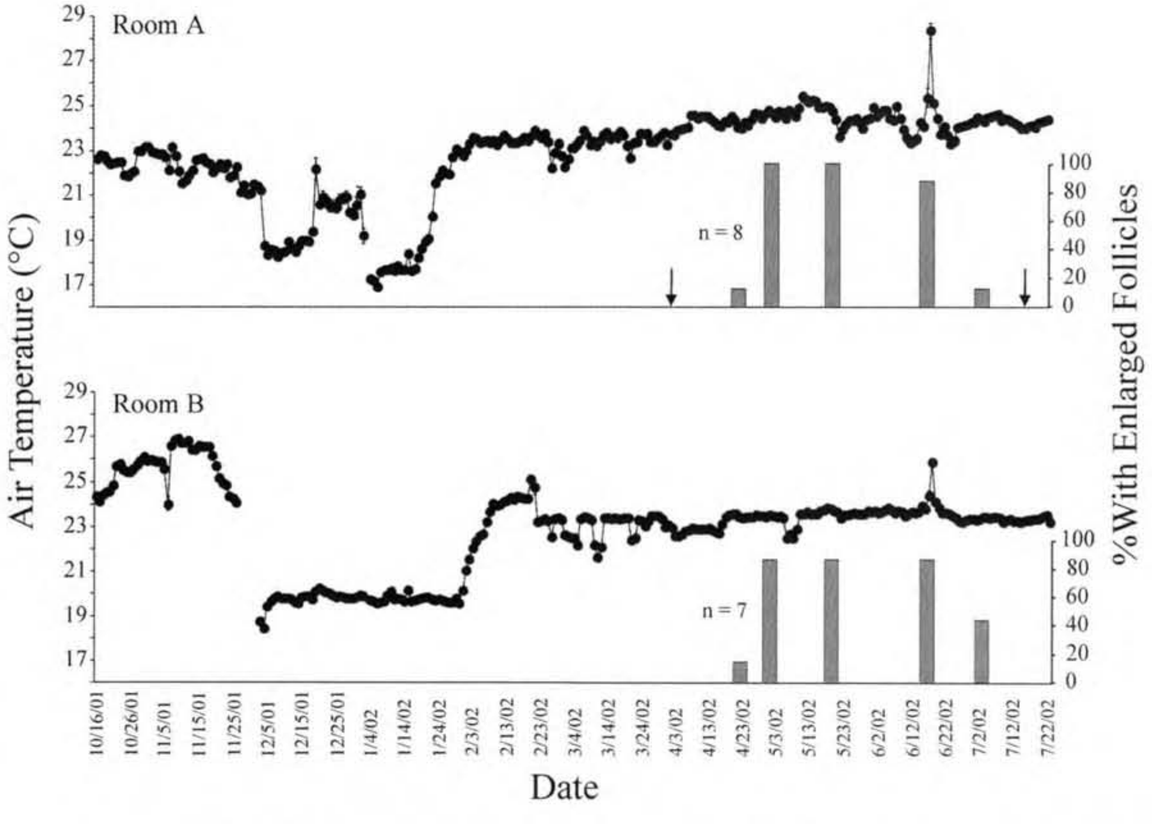

FIG. 1. Development of enlarged ovarian follicles by female brown treesnakes (*Boiga irregularis*) with respect to air temperature and date. The number of females (N) in each room is given. Palpating for the presence of enlarged follicles began 8 January 2001. Fourteen of the 15 females developed enlarged follicles. Arrows bounding the period when follicles were detected indicate the nearest examination dates (same for both rooms) where no enlarged follicles were found. Air temperatures are presented as daily means ± 1 SE. Periods of missing data were due to malfunction of data loggers.

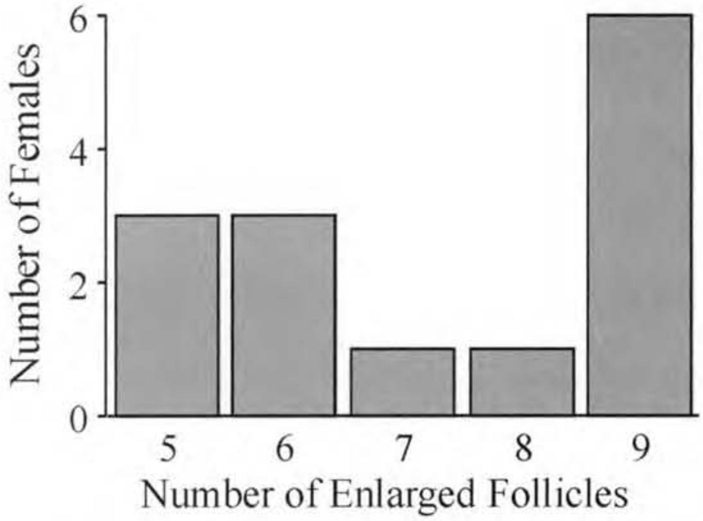

FIG. 2. Frequency distribution of the number of brown treesnake females (*Boiga irregularis*) with respect to number of enlarged ovarian follicles.

tiates a neuroendocrine reflex that is necessary for the initiation and maintenance of vitellogenesis, but this mechanism has not yet been documented in any other vertebrate species (Mendonça and Crews 1990). In the present study, it seems unlikely that the brief presence of mostly-uninterested males would induce ovarian recrudescence. In the majority of reptiles and other vertebrates, both temperate and tropical, the primary cues for ovarian recrudescence are environmental.

Why did none of our females ovulate? It is possible that palpating for follicles caused stress that resulted in resorption of follicles. Chronic exposure to stressors disrupted ovarian recrudescence in the lizard, *Mabuya carinata* (Ganesh and Yajurvedi 2002) and brown treesnakes exhibit a substantial increase in plasma levels of the stress hormone, corticosterone, in response to acute stress (Mathies et al. 2001). However, stress was an unlikely cause in the present study because females were long-term captives that appeared to be used to routine handling and cage maintenance and have previously produced viable eggs at our facilities (Mathies and Miller 2003). Thus, the stress that females experienced, if any, was presumably not appreciable or chronic. Second, if palpation was stressful, then it would have to have had a differential effect on follicular growth versus ovulation because it had no apparent effect on the former.

We suggest that follicles were not ovulated because the appropriate cue was lacking. The most likely cue would be the stimuli attendant with the physical act of mating. Induced ovulators, where coitus is thought to produce a reflex discharge of gonadotropin-releasing hormone and hence luteinizing hormone, occurs in a variety of vertebrates. Such a mechanism has not been reported in reptiles, but its presence/absence has not been well investigated. One reason mating did not occur in this study is that females may not have been in the appropriate stage of the reproductive process and thus may not have been attractive to males when we attempted to mate them. Observations from this and our other breeding studies collectively suggest that female brown treesnakes are at the height of sexually receptivity when they contain large, pre-ovulatory follicles. Recall that in the present study, mating trials were discontinued about 50 days before the first follicles were detected. Thus, females had not yet developed mature follicles when we attempted to mate them. In the first breeding attempt at our facilities, the three females that did produce eggs did so at about 35–40 days following a period when repeated successful intromissions for each female were observed (Mathies and Miller 2003), and in a third and most recent breeding attempt, we observed that ovulation (N = 6 females) occurred approximately 30 days prior to egg laying (Mathies and Miller, unpubl. data). Thus, the three females in the first study that laid eggs likely contained mature pre-ovulatory follicles when they copulated with males. Further support for the contention that male contact is necessary for ovulation comes from studies on captive reproduction of insular species of *Epicrates*. Tolson et al. (1985) demonstrated that female *Epicrates angulifer* initiate ovarian recrudescence in response to a period of cool temperatures but do not ovulate (i.e., follicles are resorbed) unless they experience extensive male courtship. This same phenomena have apparently also been observed in other species of *Epicrates* (Tolson 1994).

Induced ovulation might be expected in a system where males are common and continuously reproductive and where females do not store sperm. The Guam population of brown treesnakes meets at least two, and possibly all, of these criteria. Snakes occur at unusually high densities (Rodda et al. 1992) and no degree of seasonality of reproduction has been detected (Rodda et al. 1999). Although oviducts of Guam females have not been examined for sperm storage areas, a study on female brown treesnakes from southeastern Queensland detected no such structures (Bull et al. 1997). However, sperm storage has been inferred (but not demonstrated) in *Boiga dendrophila* (Groves 1973) and *Boiga multomaculata* (Kopstein 1938).

Induced ovulation in brown treesnake females would be adaptive in that vitellogenic individuals that go unmated would presumably be able to recoup much of their reproductive investment through follicular resorption. In our colony, females that have resorbed their follicles maintain body masses and abdominal fat body sizes similar to those when reproductive whereas females that have recently laid eggs have relatively low body masses and small abdominal fat bodies (Mathies and Miller, unpubl. data).

The hypothesis that female brown treesnakes are induced ovulators can be easily tested; one would only need to induce folliculogenesis in females and mate one group but not the other. Our findings suggest that the appropriate time to mate females (i.e., when females are most attractive to males) is when females have large, preovulatory follicles.

Venomous Reptile Bites in Academic Research

CRAIG IVANYI*
and
WILLIAM ALTIMARI
Arizona-Sonora Desert Museum
2021 North Kinney Road Tucson, Arizona 85743, USA
**Corresponding author; e-mail: civanyi@desertmuseum.org*

Many people work with venomous reptiles, both in the field and in captivity. Researchers generally have some understanding of the risks involved in working with these animals but might not have a full appreciation of the consequences of a venomous bite. Most venomous snakes have the ability to inflict temporary injury, permanent disfigurement, or death.

Card and Roberts (1996) surveyed the incidence of bites from venomous reptiles in North American Zoos. Thirty institutions maintaining venomous animals responded, 21 of which reported having staff that had been bitten by venomous reptiles, for a total of 31 bites during a 26-year period. Over 37% of the victims were between 20 and 25 years of age and had less than five years of professional experience working with venomous reptiles.

After discussions with several researchers affiliated with colleges and universities in the United States, we wondered if similar results would be found among academic institutions. In July of 2000, a questionnaire was distributed to 130 institutions across the United States. Data were gathered regarding bite frequency, bite circumstances, handling methods and protocols, bite emergency protocols, and knowledge about the availability of antivenom.

Seventy-four institutions responded, with 40 reporting research with live venomous reptiles. Eighteen reported 42 envenomations and six dry bites from a total of 20 reptile species, with two bites attributed to unnamed species (Table 1). Thirty-three of the bites were inflicted by vipers, 25 from pit vipers, while four came from elapids, 10 from colubrids, and one from an unnamed snake. Eighteen bites occurred in the laboratory and 30 in the field. Ten institutions conducted inquiries on the circumstances of the bites, which resulted in seven changing their handling protocols. A large majority of these bites (87.5%) were the result of using dubious capture and/or restraint methods, including deliberately picking up or free handling snakes, pinning snakes, handling snakes with gloves, and improper use of restraint tubes. Sixty-one percent of the bites occurred at institutions without training protocols.

Training of personnel varied widely in depth and detail. Although 23 institutions required that researchers demonstrate minimal competence with animal manipulation, 19 institutions performing research with venomous reptiles reported having no training program at all on venomous animal manipulation. Of the others with some type of training program, only 16 required physical practice and four provided a written text regarding this topic. Nineteen reported having no emergency response protocol, and 13 reported that antivenom was not kept at the institutions and that it was unavailable at local medical facilities.

Equally interesting to us are the methods by which venomous reptiles were manipulated. Thirty-one institutions reported using tongs, while 30 used hooks, and 22 employed tubes. Seventeen institutions reported pinning, and nine used leather gloves in the

TABLE 1. Species involved in bites (envenomations and dry bites).

Species	Number of bites
Agkistrodon contortrix	9 (8 envenomations/1 dry)
Agkistrodon piscivorus	1
Atheris nitschei	1
Atractaspis irregularis	1
Boiga irregularis	10
Bothrops asper	1
Boulengerina christyi	1

Unnamed genus/species	1 (dry)
Totals	48 (6 dry)

*These numbers underestimate the actual number of bites that occurred at these institutions. We are aware of several bites that were not reported.

capture of venomous reptiles. Three reported that researchers free-handled (unrestrained) venomous reptiles.

The frequency of envenomation appears to exceed that of reptile keepers in public zoos and herpetaria, even though these latter institutions house a greater number and variety of venomous species, and keeper interaction with them is more frequent and extensive. The data suggest that the number and circumstances of bites in academia correlate with inadequate training programs at these institutions. In discussions with several researchers, we have learned that bites from venomous animals are regarded by some as an inevitable result of this type of research—a view that is both erroneous and dangerous.

The data also suggest that a cavalier attitude toward working with venomous reptiles might exist among some academic researchers and that they might not be familiar with all of the protocols currently employed to prevent envenomations. Considering that these individuals might also be responsible for training future herpetologists, we believe that most researchers would benefit from developing and imparting a more cautious attitude toward manipulating venomous wildlife. They would also profit from more knowledge and training in the areas of venomous animal manipulation, as well as greater diligence in developing and employing safety protocols.

Appropriate procedures for handling venomous reptiles and medical care procedures for bite victims should be developed by institutions involved in venomous animal research. Researchers should identify local physicians familiar with snakebite treatment, plot routes to the hospital, and contact emergency personnel beforehand so that they are aware of the type of venomous reptiles involved. In case medical advice or additional serum is needed, phone numbers for poison control centers should be listed, and antivenom stocks should be kept current. If venomous reptiles are maintained in a laboratory, consideration should be given to installation of an alarm system, and development of a snakebite protocol with contact numbers for snakebite consultants, including first aid measures to be administered by co-workers. The envenomation protocol in use at the Arizona-Sonora Desert Museum is available by contacting us.

NATURAL HISTORY NOTES

The Natural History Notes section is analogous to Geographic Distribution. Preferred notes should 1) focus on observations with little human intrusion; 2) represent more than the isolated documentation of developmental aberrations; and 3) possess a natural history perspective. Individual notes should, with few exceptions, concern only one species, and authors are requested to choose a keyword or short phrase which best describes the nature of their note (e.g., Reproduction, Morphology, Habitat, etc.). Use of figures to illustrate any data is encouraged, but should replace words rather than embellish them. The section's intent is to convey information rather than demonstrate prose. Articles submitted to this section will be reviewed and edited prior to acceptance.

Electronic submission of manuscripts is requested (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Authors without the ability to send manuscripts electronically may supply hard copy instead. Figures can be submitted electronically as JPG files, although higher resolution TIFF or BMP files will be requested for publication. If figures cannot be provided in this format, you may send them to the section editor for scanning. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ssarherps.org/HRinfo.html. Manuscripts should be sent to the appropriate section editor: **Marc P. Hayes** (amphisbaenids, crocodilians, lizards, and *Sphenodon*; mhayesrana@aol.com); **Charles W. Painter** (amphibians; cpainter@state.nm.us); **Andrew T. Holycross** (snakes; holycross@asu.edu); and **James Harding** (turtles; hardingj@pilot.msu.edu).

Standard format for this section is as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother [2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. Herpetol. Circ. 29:1–82; available online at <http://herplit.com/SSAR/circulars/HC29/Crother.html>]; for Mexico as it appears in Liner [1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*, Herpetol. Circ. 23:1–113]), KEYWORD. DATA on the animal. Place of deposition or intended deposition of specimen(s), and catalog number(s). Then skip a line and close with SUBMITTED BY (give name and address in full—spell out state names—no abbreviations). (NCN) should be used for common name where none is recognized. References may be briefly cited in text (refer to this issue for citation format).

Recommended citation for notes appearing in this section is: Lemos-Espinal, J., and R. E. Ballinger. 1994. *Rhyacosiredon leorae*. Size. Herpetol. Rev. 25:22.

CAUDATA

***AMBYSTOMA* SPP. (Mole Salamanders). LOTIC BREEDING.** Breeding in *Ambystoma* salamanders is commonly associated with lentic habitats such as forested pools, ponds, and wetlands throughout North America. However, a review of Petranka (1998. Salamanders of the United States and Canada. Smithson. Inst. Press, 587 pp.) indicates that reproduction also occurs in flowing water for numerous species. Here we report additional evidence of lotic reproduction by *Ambystoma* species collected from primary headwater streams (< 259 ha watershed size) in Ohio.

Ambystoma texanum larvae were collected 17 May 2000 from two channel modified streams with agricultural land use in Union County (Allen and Jerome townships). Total length of nine voucher specimens ranged from 20.2–29 mm for the Allen Township population; and 18–26.5 mm (N = 3) for Jerome Township. Larvae of *A. barbouri* were collected 20 July 2000 from a headwater stream with intact riparian zone in Warren County, Washington Township. Body length of three voucher specimens ranged from 34–39.0 mm. A larva with TL 36.2 mm had reduced gills, which suggests the population was close to metamorphosis. The stream substrate was dominated by cobble-gravel-boulders with pools of water connected by subsurface flow. In this stream, *A. barbouri* larvae were coexisting with larvae of the southern two-lined salamander, *Eurycea cirrigera*. A large (TL 62.3 mm) and uniformly dark *A.*

barbouri larva was collected 14 June 2000 from a headwater stream in Preble County. An egg mass of the spotted salamander, *Ambystoma maculatum*, was collected 6 April 2000 (hatched 19 April 2000 at the laboratory) from a channel modified headwater stream draining a wetland in Cuyahoga County (Westlake). The hatchling was TL 10.9 mm and possessed balancers. Diameter of egg envelope was 11.0 mm.

We view the frequency of these lotic captures (about 1.6/100 primary headwater streams surveyed) to be significant given that the selection of sample sites was random and not focused toward lentic breeding habitats of *Ambystoma*. The above observations, and literature cited by Petranka (1998), suggest that headwater streams may be more important for *Ambystoma* population dynamics than commonly recognized. Future studies are needed to determine the extent that *Ambystoma* species are using headwater streams for reproduction near known lentic breeding habitats, and the degree of genetic isolation between lotic and lentic breeding populations.

We thank R. A. Pfingsten for verification of larval identifications.

Submitted by **ROBERT D. DAVIC, PAUL ANDERSON, STEVE TUCKERMAN,** Ohio Environmental Protection Agency, Division of Surface Water, Northeast District Office, 2110 East Aurora Road, Twinsburg, Ohio 44087, USA; (e-mail [RDD]: robert.davic@epa.state.oh.us).

AMBYSTOMA TEXANUM (Small-mouthed Salamander). **PREDATION**. On 23 May 2003 at ca. 1730 h I observed a Common Grackle (*Quiscalus quiscula*) pecking at an object in Coles County just W of Charleston, Illinois (T12N R9E NW1/4 Sec. 16). When I investigated, a dead *Ambystoma texanum* (56.9 mm SVL) was found in the grass with several obvious puncture wounds. Although I did not observe the grackle initiate the attack on this salamander, it was likely the cause of the salamander's death. The small-mouthed salamander otherwise looked to be unmolested. The skin was still moist as though the salamander had very recently died and may have been moving through the grass, possibly in the process of emigrating from a breeding location. It had rained the evening before and this would be the appropriate weather and season for this salamander to be moving to summer home ranges. The afternoon was warm and dry with a steady breeze.

Both species are common in this area and it is possible that this interaction occurs on a regular basis. I am unaware of any recorded observations of grackles predating small-mouthed salamanders. Dr. Chris Phillips encouraged me to report this observation. I would like to thank him for his interest and critical review of this report.

ANEIDES AENEUS (Green Salamander) AND ***PLETHODON GLUTINOSUS*** (Slimy Salamander). **NESTING OBSERVATIONS**. *Aneides aeneus* is an inhabitant of rocky areas along the Appalachian Mountain chain extending south into northern Alabama and extreme northeastern Mississippi. There is a disjunct population in southwest North Carolina and adjoining areas of South Carolina and Georgia (Petranka 1998. The Salamanders of the United States and Canada. Smithsonian Inst. Press, 587 pp.). Petranka (1998, *op. cit.*) reports that green salamanders may breed anytime during the warmer months but the majority do so in May and June with a secondary season in September and October. In Alabama, the only nests have been found in July (Mount 1975. The Reptiles and Amphibians of Alabama. Auburn Printing, Auburn, Alabama, 345 pp.). The nests of green salamanders are located within crevices of sedimentary rocks where the eggs are laid on the ceiling.

Slimy salamanders also use natural cavities in which to lay their eggs (Petranka 1998. *op. cit.*). It is believed that most oviposit in crevices beneath ground since relatively few surface nests have been found (Highton 1956. Copeia 1956:75-93; Highton 1962. Copeia 1962:597-613; Petranka 1998. *op. cit.*).

Two green salamander nests were located on 8 and 11 Sept 2002, one on each date. Additionally, a slimy salamander nest was located on 15 Sept 2002. All nests were located within DeSoto State Park (Dekalb County) in northeast Alabama. The first green salamander nest was found in a sandstone boulder 500 m northwest of the campground entrance gate of DeSoto State Park. The brood crevice was on the west face of the boulder. The crevice itself was ca 1.0 m from the ground and 1.5 m in horizontal length. The entrance to the brood chamber was located at the northern end of the crevice. This entrance was horizontally oval with a depth of about 15.4 cm. The eggs were laid at a depth of about 5 cm. Only 8 eggs were visible. The second green salamander nest was located about 700 m west of the first nest. The brood chamber was located on the north face of a sandstone boulder. The chamber was tubular in overall shape and ca. 1.5 m from the ground. The chamber was ca. 12.7 cm deep and eggs were ca. 10 cm from the entrance. The overall shape of the egg masses of both green salamander nests was that of an upside down triangle, or a cluster of grapes.

From the first observations on 8 and 11 Sept 2002, to 28 Sept 2002 there was little change. A total of six observations on the first nest and five on the second were made. The females were always present and in contact with at least some of the eggs. On at least one occasion the female from the first green salamander nest was located on the ceiling of the crevice, otherwise all females were located on the brood chamber floor. On 28 Sept 2002, the eggs of the first green salamander nest started hatching. The larvae were fully formed and attempting to break free of the egg membranes. The larvae responded to touch by wriggling. It was not until 4 Oct 2002 that the larvae had hatched completely and were moving about the brood chamber. The female was present and actively attacked, with her snout, any probe presented to her. Prior to hatching she was more likely to retreat than attack probes presented to her. On 20 Oct 2002, a mature male was spotted at the southern end of the crevice of the first nest site. He was not observed at any other date. The female and hatchlings dispersed by 7 Nov 2002. There were at least 13 hatchlings from this brood.

The timetable for the second green salamander nest was slightly different. On 4 Oct 2002, 3 eggs were still present with fully formed larvae within. The larvae were completely hatched by 13 Oct. The female of this nest was not present by 20 Oct while the larvae remained. By 7 Nov, the larvae had also dispersed. At least 8

hatchlings were produced from this nest. A total of 12 observations were made at the first green salamander nest and 11 were made at the second.

The slimy salamander nest was first located on 15 Sept 2002 in a sandstone rock wall ca. 25 m north of the second green salamander nest. The crevice was ca. 1.5 m from the ground, horizontal, and ca. 1.0 m long. This crevice was about 45.7 cm deep. The eggs were laid at a depth of ca. 30 cm. The egg cluster was elongate, in the shape of an "L" lying on its "back." Ten eggs could be seen. The larvae had hatched by 6 Oct 2002, however due to the morphology of the crevice interior only one hatchling could be seen. The female had dispersed by 7 Nov, and the hatchling(s) were present until 22 Nov. No more that one hatchling was visible. A total of 12 observations were made at this nest.

ANURA

COCHRANELLA ALBOMACULATA (NCN). **REPRODUCTION**. Centrolenids are neotropical riparian frogs that breed primarily throughout the wet season (Ibañez et al. 1999. The Amphibians of Barro Colorado Nature Monument, Soberanía National Park and adjacent areas, Editorial Mizrachi and Pujol, Panamá. 187 pp.). *Cochranella albomaculata* is found from Honduras to Colombia (Savage 2002. The Amphibians and Reptiles of Costa Rica, Univ. Chicago Press, Chicago 934 pp.). Here we report a shift in the reproductive behavior and oviposition site of *C. albomaculta* coinciding with the onset of the dry season. *Cochranella albomaculata* is very abundant in most of the smaller creeks that feed into the upper Río Jaris basin at the Reserve of the Universidad de la Paz (Costa Rica) in the rainy season. During the wet season males and egg clutches are distributed throughout the stream channel. Females deposit eggs on the upper surface of the vegetation over streams. At the beginning of the dry season of December 2001 and December 2002, we observed a shift at this site. A large aggregation of males and egg clutches (N = 53; Dec 2002) on rocks were seen in the splash area of two waterfalls. Calling males and two egg clutches were present on a big boulder in Río Jaris. These observations suggest that *C. albomaculata* utilizes these wet splash zones to prolong breeding during part of the dry season.

We thank Jeanne Robertson, Andrew Crawford, and Jay Savage for comments on the manuscript.

RANA AURORA AURORA (Northern Red-legged Frog). **VOCALIZATION**. Leonard et al. (1997 Northwest. Nat. 78:73–74) described one instance of non-breeding season vocalization involving 2 male *Rana a. aurora* from a terrestrial location on the NW side of Fiander Lake, Pierce County Washington, USA on 1 Nov 1996. Confirmation of sex or terrestrial position was not possible as the frogs were not visually located (Leonard et al., *op cit.*). Such confirmation is important because *Rana a. aurora* calls can be highly ventriloquial (Licht 1969. Can. J. Zool. 47:1287–1299), and *Rana a. aurora* have been described as typically vocalizing from submerged positions during reproduction (Licht, *op. cit.*), a pattern that has even been used to support the systematic differentiation between red-legged frog taxa (Hayes and Miyamoto 1984. Copeia 1984:1018–1022). Further, the lone episode of non-breeding vocalizations that Leonard et al. (*op. cit.*) described for *Rana a. aurora* could be perceived as atypical. Here, we confirm male northern red-legged frog vocalization from terrestrial locations outside the reproduction season, and show that the pattern may be commonplace. All observations were made in the vicinity of Olympia, Washington.

At 0640 h on 20 Aug 2002, one of us (MPH) heard distinctive weak, clucking vocalizations matching those of male *R. a. aurora* advertisement calls (*fide* Davidson 1995. Frog and Toad Calls of the Pacific Coast. [audio compact disc]. Library of Natural Sounds, Cornell Laboratory of Ornithology, Ithaca, New York) coming from near a small rural pond in NW Olympia described elsewhere (Hayes and Hayes 2003. Herpetol. Rev. 34:45–46). Vocalizations, involving 4–8 note series made at irregular intervals during a 10-min observation period, were traced to a male *R. a. aurora* concealed under a sword fern (*Polystichum munitum*) 0.5 m from the pond. The male was identified from a unique toe clip as an individual that had been released in this pond on 5 May 2002 (Hayes and Hayes, *op. cit.*). At 1400 h on 24 Aug 2002, two of us (CBH, MPH) found this same male vocalizing over a roughly 12-min interval from a concealed position beneath another sword fern ca. 1.4 m from the pond. We heard this same male and a second marked *R. a. aurora* male, also described elsewhere (Hayes and Hayes, *op. cit.*), call on no fewer than 13 other occasions over the interval 31 Aug–23 Sept 2002 during daylight hours. On 11 of these occasions, calling males were traced to concealed positions in terrestrial locations under sword ferns 0.5–3 m from the pond.

A second set of observations was made between 1340–1510 h on 21 Sept 2002, along the margin of a 4-ha patch of red alder (*Alnus rubra*) with an understory of mostly dense sword ferns in west Olympia (47°04'06"N, 122°58'12"W; elev. 49 m). Almost immediately upon entering this alder grove, which was largely sheltered from significant noise, MPH heard the weak calls of *R. a. aurora*. During the 1.5-h search of a ca. 80-m diameter circular area of this grove, over 24 calling episodes were heard. Four were tracked to calling males, all of which were in entirely concealed calling stations, three under sword ferns and the fourth in a small space under small woody debris. The four males found were 52–57 mm SVL and had small, poorly developed nuptial pads. Each male found was also located within 8 m of the position of at least one of the others.

On 19 Sept 2002 at 1900, JPS also heard calls matching those of male *R. a. aurora* advertisement calls from a concealed terrestrial site in the Steamboat Island area ca. 10 km E of Olympia (47°06'16"N, 122°59'19"W; elev. 5 m). This site has a mature western red cedar-big leaf maple (*Thuja plicata-Acer*

macrophyllum) forest with a sword fern-dominated understory and was the site of an intensive study of *R. a. aurora* by JPS. In this case, the calling individual was audible from a distance of ca. 5 m, and was heard from the location of a second non-calling frog. Both were > 60 m from the nearest freshwater source. Notably, the vicinity of these 2 frogs had been regularly, thoroughly searched for *R. a. aurora* during the summer, with none found until 11 Sept, when the non-calling frog, (56 mm SVL, 19 g, sex undet.) was caught and pit-tagged. Finding the aforementioned 2 frogs on 19 Sept was followed by finding 4 frogs (including the tagged frog and 3 others [49-69 mm SVL; 10-34 g, sex undet.]) on 28 Sept in the same vicinity, suggesting some sort of staging.

Vocalization by male *R. a. aurora* from concealed locations outside of the breeding season may be commonplace. Northern red-legged frog males are well known to have weak vocalizations (Hayes and Krempels 1986. Copeia 1986:927-936; Leonard et al. 1993. Amphibians of Washington and Oregon. Seattle Aubudon Society, Seattle, Washington. 168 pp.; Licht, *op. cit.*) that have been described by some as barely audible at a distance of 0.5 m (Nussbaum et al. 1983. Amphibians and Reptiles of the Pacific Northwest. University Press of Idaho. 332 pp.), and as such, they may be easily missed. Several aspects of these observations warrant exploration. Both males from the NW Olympia pond were known to have become sexually mature within the month we heard the first calling (Hayes and Hayes, *op. cit.*) and the sizes and incompletely developed nuptial pads of the other calling males that were found implies that younger males were involved. Younger individuals may be easier to detect because of their presumably more limited predator experience, so understanding whether a younger age bias really exists in such terrestrial calling may be difficult. Second, context of terrestrial calling remains vague. Staging, which the Steamboat Island observation implies, may be a prelude to the poorly understood seasonal fall migration that northern red-legged frogs undertake (MPH, P. Ritson, JPS, unpubl. data). Terrestrial calling may facilitate this behavior. Lastly, awareness that vocalization from concealed terrestrial locations is not infrequent may require re-evaluation of *R. a. aurora* reproductive behavior. In particular, the ventriloquial nature of *R. a. aurora* calls (Licht, *op. cit.*) may require reassessment of the degree to which males call from submerged locations during the breeding season.

SCAPHIOPUS HOLBROOKII (Eastern Spadefoot). **DIURNAL BREEDING.** *Scaphiopus holbrookii* is generally considered to be a nocturnal species (Bragg 1945. Am. Midl. Nat. 79: 52–72; Behler and King 1979. National Audubon Society Field Guide to North American Reptiles and Amphibians. A. A. Knopf, New York, 743 pp.). This is based both on behavioral observations and morphology (e.g. vertical pupils).

Heretofore, all of our observations of this species on Long Island had been at night. On 27 May 2003, we observed diurnal breeding congregations of *S. holbrookii* at the Brookhaven National Laboratory, Upton, Suffolk County, New York, USA (40°52'20"N, 72°52'04"W). At ca. 1030 h, the skies cleared after six days of cloud cover, cool temperatures (six day mean = 11.8°C), and 10 cm of rain, 7.3 cm of which fell on 26 May. By 1100 h, after 30 min of direct sunlight and rapidly increasing temperatures, the breeding calls of *S. holbrookii* initiated in nearly all the temporary wetlands within the 2,130 ha site. The temperature was 18.1°C when toads started calling. Intense breeding activity continued throughout the day, declined in late afternoon, increased again after sunset, and continued beyond 2100 h. The next morning no *S. holbrookii* were observed. The arrival of optimal breeding conditions subsequent to six days of heavy precipitation and suppressive temperatures (4.6°C below normal) coupled with extreme draught conditions the previous year likely contributed to this explosive-diurnal breeding episode. On 5 June 2003, after 5.8 cm of rain the prior day, JAF again heard the diurnal calls of male *S. holbrookii* coming from two wetlands.

TESTUDINES

CHELONOIDIS CHILENSIS (Argentine Tortoise). **PREDATION.** *Chelonoidis chilensis* is one of three terrestrial Argentinian tortoises contained within the family Testudinidae. It is distributed from SW Bolivia and Occidental, Paraguaya to the Colorado River and the boundary of Rio Negro Province, Argentina (Cei 1993. Mon. 14 Mus. Reg. Sci. Nat. Torino, 949 pp.). This species has also been reported from the eastern portion of the San Juan Province, Argentina by the Departament of Valle Fértil (Avila et al. 1998. Cuad. Herp. 12:11–29). It has been recently designated as "Threatened" in Argentina (Lavilla et al. 2000. Asoc. Herp. Arg., 97 pp.) and has the status of "Maximum Priority of Conservation" in Ischigualasto Park, San Juan Province (Acosta and Murúa 1998. Multequina 7:49–59).

Here we report the first incidence of predation on *C. chilensis* in Provincial Ischigualasto Park, Valle Fértil Department, San Juan, Argentina (30°05'S, 67°55'W). On 10 April 2001, in the North Sector of Overo Mountain, an adult *C. chilensis* that had recently been killed was found. The puma (*Puma concolor*) and the fox (*Pseudalopex griseus*) are the primary predators within the park (Acosta and Murúa 1999. Multequina 8:121–129). The injuries on the carapace of the tortoise (size of canine mark, space between canine) indicate that they were made by *P. concolor*. The specimen was deposited in the Herpetological Collection of the Instituto y Museo de Ciencias Naturales, Universidad Nacional de San Juan, Argentina (IMCN-UNSJ 492).

We are grateful to J. Marquez for supplying us with the tortoise specimen.

CLEMMYS INSCULPTA (Wood Turtle). **HATCHING FAILURE**. Hatchlings of many turtle species, instead of hatching and emerging from the nest before winter, may overwinter in the nest and emerge the following spring (Gibbons and Nelson 1978. Evolution 32:297–303). Wood turtle *(Clemmys insculpta)* hatchlings are not known to delay emergence and overwinter in the nest (Harding and Bloomer 1979. Bull. New York Herpetol. Soc.15:9–26; Lovich et. al. 1990. Can. J. Zool. 68: 672–677). This assertion is based on abundant records of wood turtle hatchlings emerging from nests in the months of August through October, and no records of hatching or recent hatchlings in spring or early summer. Here, we report that wood turtle embryos in a natural nest did not complete development before winter in a cool year and did not survive over winter.

On 15 June 1993, we observed a wood turtle creating a nest in St. Louis County, Minnesota, USA. The nest was located on a sandy cutbank, 3 m from the main channel of a river and 2 m above water, and on a fully exposed site with a 34° slope and southwestern aspect. Herbaceous cover surrounding the nest site was 50% red raspberry *(Rubus idaeus)*. We checked the nest site on 29 September, 5 October, 15 October, and 21 October 1993, and found no evidence of disturbance on the nest surface. We excavated the nest on 21 October 1993 and counted 11 eggs; 10 appeared viable and one was shriveled. One of the 10 apparently viable eggs was accidentally slit during excavation. This egg contained a live turtle embryo. This egg and the nine good eggs were returned to the nest cavity and recovered with sand. A wire basket was staked over the nest to exclude nest predators.

We revisited the nest on 9 May 1994, and found it and the basket exclosure intact. We removed the 10 eggs, some of which now appeared dead, placed them in moist sand, and transported them to a facility where they were stored at room temperature. On 9 June, we slit the shell of each egg and examined each embryo for signs of life but found none. One badly deteriorated egg was discarded. The nine remaining eggs were preserved in formalin. Upon close examination at a later date, all eggs appeared to have been decayed at the time of preservation. Two eggs lacked any evidence of development. These eggs could have been infertile, or their embryos could have died in the oviducts prior to laying. One egg appeared to contain an early embryo; however, it was too decayed to locate with precision. The egg appeared to have a subgerminal space, which is characteristic of fertile eggs. Two eggs contained Yntema stage 24 embryos, which are advanced but smaller than term embryos and probably incapable of surviving a premature hatching. The remaining four eggs contained stage 25 embryos; that is, they were very close to term size and almost ready to hatch and leave the nest.

Weather records were available from a nearby station for the period 1986 to 2001. Air temperatures from May through September in 1992 and 1993 were the coldest for this period. In 1993, most nests were constructed during the second week of June, many hatchlings did not leave their nest until the last half of September, and hatchlings from two nests left their nests during the first two weeks of October. Compared to other nests on the cutbank, the single nest we report on was clearly late in completing incubation. Inspection of photographs showed that this nest site had the most herbaceous vegetation near the nest site. Thus, in addition to 1993 being a cool year for incubation, this nest site was probably more shaded than all other nest sites.

Our observations of at least one live embryo on 21 October, as well as six advanced-stage embryos the following spring, suggest that 6 of the 10 eggs narrowly missed hatching before winter. Furthermore, the appearance of eggs in fall and the following spring, and their state of decay on 9 June suggest that none were alive by spring. Thus, overall, our observations corroborate other evidence, which suggests that wood turtle embryos must complete development and leave their nest before onset of winter to survive in more northern latitudes.

EMYDOIDEA BLANDINGII (Blanding's Turtle). **MAXIMUM SIZE.** The maximum straight line carapace length (CL) for *E. blandingii* reported is 27.4 cm (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington. 578 pp.). Here, we report on the measurement of a larger individual. On 10 June 2001, an adult male *E. blandingii* was captured during a herpetological species inventory survey in Lake Maria State Park, Wright County, Minnesota, USA. The turtle was measured at 28.4 cm CL. The turtle was marked and released after data was taken. A slide of the record is deposited in the James Ford Bell Museum, University of Minnesota, Minneapolis (accession no. P-248).

GOPHERUS BERLANDIERI (Texas Tortoise). **MORTALITY**. During mammalian wildlife research on ranches in Webb County, Texas (Engeman et al. 2002. Wildl. Res. 29:85–90), we observed two common sources of mortality for *Gopherus berlandieri* (listed as a threatened species in Texas) based on locations of shell remains. First, the ranches had a network of primary dirt roads crisscrossed by smaller one-lane roads/tracks. Shell remains (often in poor condition) were frequently discovered adjacent to the roads in this network, suggesting collisions with vehicles as the source

of mortality. Vehicles have been well-documented as hazards for the related *G. agassizii* (e.g., Luckenbach 1982. *In* Bury [ed.], North American Tortoises: Conservation and Ecology, pp. 1–38, USFWS Wildl. Res. Rpt. 12; Boarman and Sazaki 1996. *In* Evink et al. [eds.], Trends in Addressing Transportation Related Wildlife Mortality, pp. 179–184, State of Florida Dept. Transportation, Tallahassee, Florida). The other common location for discovery of tortoise shell remains was along fences constructed with woven field fencing at the bottom. The tortoises apparently became entangled in the fence wires and were unable to free themselves. We observed no shell remains away from these human constructions, despite extensive work in natural habitat.

Submitted by **RICHARD M. ENGEMAN** (e-mail: Richard.M.Engeman@aphis.usda.gov) and **MICHAEL J. PIPAS**, USDA/Wildlife Services, National Wildlife Research Center, 4101 LaPorte Avenue, Fort Collins, Colorado 80521-2154, USA; and **HENRY T. SMITH**, Florida Department of Environmental Protection, Florida Park Service, 13798 S.E. Federal Highway, Hobe Sound, Florida 33455, USA.

HEOSEMYS GRANDIS (Giant Asian Pond Turtle). **ANOPHTHALMIA**. Abnormalities and malformations are well documented in turtles from some regions but not others, especially Asia. Most reports are on shell deformities (e.g., Lynn, 1937. Amer. Nat. 71:421–426; Nixon and Smith 1949. Turtox News 27:28–29; Rhodin et al. 1984. Brit. J. Herpetol. 6:369–373; Saumure 2001. Chelonian Cons. Biol. 4:159). Others refer to abnormalities of the head, limbs, and shells of hatchlings (e.g., Ewert 1979. *In* Harless and Morlock [eds.], Turtles: Perspectives and Research, pp. 333–413, Wiley InterScience, New York). A large sample of *H. grandis* was among the 10,000 turtles putatively from Malaysia that was confiscated by Hong Kong authorities on 11 December 2001. Approximately 3900 turtles were shipped to the United States in January 2002 for processing and distribution to rescue centers, zoos, veterinarians, and university research programs (Hudson and Buhlmann 2002. Turtle and Tortoise Newslett. 6:11–14). A total of 355 *H. grandis* was received in the three shipments (Ades and Crow 2002. Turtle and Tortoise Newslett. 6:2–7). During the triage, marking, and measuring process we discovered that one unsexed adult (347 mm CL, 299 mm PL, 5.7 kg, marked 289) was missing its right eye. The abnormality appears to be congenital, as normally pigmented skin lies over the orbit and there was no evidence of injury or loss (Fig. 1). Palpation revealed the bony orbit but no eye mass. This is the first report of natural anophthalmia for this poorly known freshwater turtle.

FIG. 1. *Heosemys grandis* exhibiting congenital anophthalmia.

PHRYNOPS GIBBUS (Gibba Turtle). **TRAP-HAPPY BEHAVIOR.** Most estimates for determining the size of a population using mark-recapture methods assume equal capture probability among individuals. Behavioral differences between or within species or flawed trap design or placement might bias sampling with regard to this assumption (Lindeman 1990. J. Herpetol. 24:78–81). Kazmaier et. al. (2001. J. Herpetol. 35:410–417) attributed a shift from biased to unbiased captures of *Gopherus berlandieri* from early to late summer to sexual differences in reproductive behaviors. Sampling biases have been reported in studies of *Chrysemys picta* (Ream and Ream 1966. Amer. Midl. Nat. 75:325–338; Frazer 1990. Copeia 1990:1150–1152) and *Terrapene carolina* (Langtimm 1996. Herpetologica 52:496–504). Koper and Brooks (1998. Can. J. Zool. 76:458–465) identified flaws in several different sampling techniques and population size estimators, and found no method that was completely unbiased.

The present study documents an apparent example of extreme trap-happy behavior, i.e. where previously-marked individuals are

TABLE 1. Dates of capture and recapture in 2001, sex, carapace length, and plastron length, for an Ecuadorian population of *Phrynops gibbus.*

	Sex	Carapace length (mm)	Plastron length (mm)	Date of first capture	Date(s) of recapture
Turtle #1	female	165	135	21 Jan	19 Feb
Turtle #2	male	163	143	21 Jan	23 Jan, 31 Jan, 4 Feb, 10 Feb, 22 Feb
Turtle #3	male	206	177	21Jan	10 Feb
Turtle #4	male	192	167	29 Jan	2 Feb, 8 Feb, 17 Feb
Turtle #5	female	185	159	10 Feb	

more prone to subsequent captures than unmarked individuals. The study was conducted in the upper Napo region of Ecuador near Tena (0°59'S, 77°49'W) at Jatun Sacha Reserva Biología during January–March 2001. A population of *Phrynops gibbus* was sampled using a hoop net baited with chicken parts. Measurements were taken of the carapace and plastron length of each individual. The sex of each turtle was determined by examination of pre-cloacal tail length. Turtles were marked using nail polish with the original intent of determining population size; however, no estimates were possible due to a high incidence of trap-happy behavior. Four of the five individuals captured were recaptured one to five times (Table 1). Potential trap-happy or trap-shy behavior needs to be taken into consideration for estimates based on an assumption of equal capture probability.

LINDEMAN,** Department of Biology and Health Services, 150 Cooper Hall, Edinboro University of Pennsylvania, Edinboro, Pennsylvania 16444, USA.

TERRAPENE CAROLINA CAROLINA (Eastern Box Turtle). **POST MORTEM INVOLUNTARY RESPONSE**. Although the ability of turtles to respond to stimuli long after death has been reported in popular literature (Coniff 1999. National Geographic, Mar. 1999:118–129), to my knowledge no detailed accounts of such behavior exist in peer-reviewed literature.

On 18 October 2002 at ca. 1300 h an adult male box turtle was found on a road in Greene County, Virginia, USA. The anterior half of the head was crushed, presumably by the tire of a vehicle. The blood present on the road and around the trauma had not coagulated, indicating the wounds were recently inflicted. The turtle responded to my touch by quickly withdrawing limbs and tail into its shell and partially closing the plastral hinge. In an effort to end perceived suffering, the turtle was quickly decapitated and left in a shaded, outdoor area. At regular intervals I checked the turtle's headless body for response to stimuli by touching the rear limbs with a small twig. At 48 h post-decapitation, the turtle responded as strongly as it did before decapitation. Subsequent tests resulted in lessened response to stimuli, that is, limbs and tail being only partially retracted and at a slower rate of movement. More than five days after finding the turtle, the last perceptible movements were recorded at 122 h post-decapitation.

Submitted by **WILLIAM D. BROWN**, Blue Ridge Biological, 978 Bull Yearling Road, Stanardsville, Virginia 22973, USA; e-mail: wbrown@blueridgebiological.com.

TERRAPENE CAROLINA CAROLINA (Eastern Box Turtle). **DIET**. Hatchling box turtles typically retain a portion of their yolk sac externally upon hatching (Ewert 1985. *In* Gans et al. [eds.], Biology of the Reptilia. Vol. 14. Development, pp. 75–267, John Wiley and Sons, New York). This yolk sac is usually absorbed within a week post hatching and provides the hatchling with nourishment during its first few days of life and through the oncoming winter (Dodd 2001. North American Box Turtles, A Natural History. University of Oklahoma Press, Norman. 231 pp.). Here, I report a previously undocumented behavior that might provide hatchling box turtles with an additional source of nutrition before exiting the nest.

An adult *T. c. carolina* was observed nesting in Anne Arundel County, Maryland, USA, during a light rain in the early evening hours of 16 June 1999. A total of six eggs were deposited. Several days later, the nest was excavated in order to remove 3 eggs for artificial incubation. Using the natural nest as model, an artificial nest was constructed in a glass aquarium allowing for the hatching process to be observed and photographed. The eggs were incubated in this setup at 26°C. All 3 eggs pipped on 25 August 1999. During the hatching process, one hatchling was observed to repeatedly bite at and consume the clear, viscous, albumin surrounding it within the egg. While it is not clear if the biting was merely an effort to help free the turtle from the egg, albumin was consumed during this process and likely served as a source of nutrition.

TERRAPENE CAROLINA CAROLINA (Eastern Box Turtle). **INJURIES.** The life history and ecology of a population of *Terrapene c. carolina* were studied from 1980–1998 at the Mason Neck National Wildlife Refuge, Fairfax County, Virginia, USA (38°67'N, 77°14'W) (Boucher 1998. Population, Growth and Thermal Ecology of the Eastern Box Turtle, *Terrapene carolina carolina* [L.], in Fairfax County, Virginia, Ph.D. Dissertation, George Mason University, Fairfax, Virginia, 228 pp.). Among the parameters noted for individual box turtles were injuries to the exposed shell and body. An injury is here defined as any unnatural physical damage to an individual that might have been caused by normal daily activity, encounters with predators, or resulting from refuge management practices. Developmental or genetic deformities, such as missing cervical scutes or subdivision of shell scutes were not considered. Chipped marginals, presumably resulting from normal movements or falls, were displayed by most adult box turtles in the population, and thus were omitted from the analysis.

Data on injuries were collected from 510 individual *T. carolina* at Mason Neck. Only 50 (9.8%) of the turtles were injured; 460 (90.2%) turtles were injury free. Analysis by sex showed that 22 (44%) of the injured turtles were females and 28 (56%) were males. Qualifying injuries, as outlined above, were placed into seven categories, here with the number of turtles showing that injury: predator teeth marks on any part of the turtle, 14 (2.75%); damaged shell, 9 (1.76%); missing legs, 6 (1.18%); swollen tympanum or cyst, 4 (0.78%); blind eye, 3 (0.59%); shell rot, 1 (0.19%); and other injuries (missing scutes or tails, abrasions, burns), 13 (2.55%). Up to 64% of the injuries (e.g., teeth marks, missing limbs, other shell damage) could have been caused by predation attempts. Raccoons (*Procyon lotor*) are common on the property and are known turtle predators, but other species are also possible suspects (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington, D.C., 682 pp.). Infections or parasitism (swollen tympanums; two recaptured later had recovered fully) accounted for another 4 (8%). Survivorship is difficult to ascertain because many of the injuries were not new when ob-

served. Assuming, however, those injured were residents with equal probability of recapture, and that recapture at least one year later indicated complete recovery (survivorship), possibly as many as 36% survived their injury. Box turtles are known to have great shell regenerative capabilities (Rose 1986. Southwest. Nat. 31:131–134; Smith 1958. Turtox News 36:234–235), and can apparently recuperate from other injuries as well.

Data on injury rates in a population are scarce in the literature (see Dodd 2001. North American Box Turtles: A Natural History. University of Oklahoma Press, Norman, 231 pp.). However, we can conclude from the Mason Neck data that injuries do occur in this population and that many box turtles are able to survive them.

SERPENTES

ANTILLOPHIS ANDREAE (Black and White Racer, Jubito). **DIET.** Schwartz and Henderson (1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions and Natural History. Univ. Florida Press, Gainesville. 720 pp.) stated that the diet of *Antillophis andreae* includes frogs of the genus *Eleutherodactylus* in a frequency of 41.2 % (in sample of 17 prey items). Our observations confirm the statement of these authors and include a new prey genus to the diet of *A. andreae.*

The stomach contents of a specimen (368 mm SVL) collected in Altiplanicie de El Toldo, Holguín Province, Cuba, on 3 June 1997 contained two specimens of *Eleutherodactylus* sp. (10 and 15 mm SVL). Another specimen was observed from this locality on 26 September 1998 eating an adult specimen of *E. dimidiatus*, and a third individual (266 mm SVL) was collected in Sabana, Maisí, Guantánamo Province, Cuba, as it was swallowing an adult *E. atkinsi* (20 mm SVL) on 14 April 1998.

A similar observation was made in the San Juan River, Santa María, Santiago de Cuba Province, on 15 August 1997 when an adult specimen of *A. andreae* (ca. 300 mm SVL) was found swallowing a juvenile *Bufo peltacephalus* (ca. 20 mm SVL). The last species has not been recorded previously as prey of *A. andreai*.

Specimens were deposited in the herpetological collection of BIOECO, Santiago de Cuba (BSC.H 1011, 1729, 1757). I thank Luis F. de Armas and Yoenris Oliveros for the donation of specimens collected by them, Iliana Boza for English translation, and Renata Platenberg for reviewing this note.

ANTILLOPHIS ANDREAE (Black and White Racer, Jubito). **REPRODUCTION**. Schwartz and Henderson (1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions and Natural History. Univ. Florida Press, Gainesville. 720 pp.) reported the laying of three eggs (6.0 x 19.3 mm) by a female *Antillophis andreae* in April. On 3 June 1997 a female *A. andreae* was collected in Alto de la Calinga, Sierra de Moa, Holguín Province, Cuba. The specimen was kept in captivity and laid three eggs on 10 June 1997. The female had a snout–vent length of 310 mm and the egg measurements were 31.0 x 9.2 mm, 30.1 x 8.1 mm, and 31.2 x 8.6 mm, respectively. The coloration of the eggs was off-white. Another clutch of this species was observed in Altiplanicie de El Toldo, Moa, Holguín Province, Cuba on 14 November 1997. This clutch was comprised of four hatched eggs deposited under a stone measuring ca. 250 x 200 mm. The eggs were off-white with longitudinal apertures characteristic of colubrid eggs. The form, size, and coloration support assignment of this clutch to *A. andreae*.

The specimen was deposited in the herpetological collection of BIOECO, Santiago de Cuba (BSC.H 1012). I thank Iliana Boza for helping me with English translation and Renata Platenberg for reviewing this note.

BOTHROPS CAMPBELLI (Campbell's Lancehead). **DIET**. The recently described pitviper, *Bothrops campbelli* Freire Lascano 1991, is distributed along the western versant of the Cordillera Occidental of the Andes in Colombia and Ecuador (Kuch 1997. Bull. Zool. Nomencl. 54:245–249) and inhabits lower montane wet and cloud forests. The genus *Bothrops* is widely distributed in most of Central and South America; however, reports on diet are few and mostly anedoctal (Campbell and Lamar 1989. The Venomous Reptiles of Latin America Comstock-Cornell University Press, Ithaca, New York, 425 pp.; Perez-Santos and Moreno 1991. Serpientes de Ecuador. Monografie Museo Regionale di Scienze Naturali, Torino XI, Italy, 538 pp.). Additionally, there is only one report on the diet of *B. campbelli*. That report documents *B. campbelli* preying on a rat-sized rodent (Freire and Kuch 2000. Herpetol. Rev. 31:45). Herein, I present an additional and exceptional prey item for *B. campbelli* and for the genus *Bothrops*.

Examining herpetological collections in Quito, I found an adult male *B. campbelli* from San Francisco de Las Pampas, province Cotopaxi, Ecuador, collected during December 1989 (ca. 0°25'S, 78°58'W, 1600 m elevation) measuring 550 mm snout–vent length, and 852 mm total length. The snake had swallowed an adult *Caecilia* sp. ca. 350 mm total length. The *Caecilia* sp. was folded within the snake's stomach and had its tail and head positioned toward the anterior portion of the snake's stomach. Gonads and internal organs of the *Caecilia* sp. were poorly preserved and thus prevented accurate sex determination. The *Caecilia* sp. specimen belongs to a taxon that is currently under revision (George Fletcher, pers. comm.). The snake (QCAZ 1087) and the *Caecilia* sp. (QCAZ 17917) are deposited in the Museo de Zoologia, Pontificia Universidad Catolica del Ecuador, Quito. The genus *Caecilia* is common in this region; however, it has never been reported as prey for pitvipers or other snakes.

Luis A. Coloma, Giovanni Onore, and Santiago R. Ron (PUCE) kindly provided logistic support. George Fletcher identified the caecilian. I thank the staff and the students of Departamento de Ciencias Biologicas for their friendship. Fernando Dini (DEEE, Pisa University) granted travel to Ecuador.

BOTHROPS JARARACUSSU (Jararacussu). **OPHIOPHAGY**. Pitvipers of the genus *Bothrops* are diet generalists, feeding both on endothermic and ectothermic prey (Martins et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publ., Eagle Mountain, Utah). The most important ectothermic prey are frogs, lizards, and centipedes, whereas snakes are unusual prey. At least nine species of *Bothrops*, including *B. jararacussu*, eat snakes occasionally (Martins et al., *op. cit.*). Here we report on a *B. jararacussu* found swallowing a snake in the wild.

A *B. jararacussu* female (SVL = 920 mm, tail = 121 mm, mass = 305 g, IB 63886) was found during the morning of 4 June 2001 on a dirt road crossing a stretch of Atlantic forest at Juquitiba, São Paulo (23°57'S, 47°03'W), southeastern Brazil. The collector (L. A. Kobata) related that a portion of the pitviper's prey (ca. 30 cm) protruded from its mouth and that its body was wrinkled. The pitviper was collected and put into a box, where it disgorged a male individual of the arboreal colubrid, *Chironius bicarinatus* (SVL = 950 mm, tail = 412 mm, mass = 220 g, IB 63887). The prey/predator mass ratio (0.72) was high (cf. Martins et al., *op. cit.*).

Although viperids have the ability to subdue and ingest enormous meals (Greene 1992. *In* Campbell and Brodie [eds.], Biology of the Pitvipers, pp. 107–117. Selva, Tyler, Texas), the snake prey was much longer than its predator. The excessive length of prey likely hindered the movements of the pitviper, and caused the wrinkles on its body. It is possible that due to the elongate form of this particular prey type, the predator had difficulty to assess the actual body length of its prey. The prey had signs of hemorrhage in five distinct parts of its body. Strike with bite and release is the usual tactic employed by snakes of the genus *Bothrops* when preying on rodents (Sazima 1992. *In* Campbell and Brodie [eds.], Biology of the Pitvipers, pp. 199–216. Selva, Tyler, Texas), whereas frogs are held after the initial strike until swallowed (Sazima 1991. Copeia 1991:245–248). Ectothermic prey such as lizards and snakes are presumably captured using the bite and hold tactic. *Chironius bicarinatus* is an agile and irritable snake that readily retaliates against attacks (Sazima and Haddad 1992. *In* L. P. C. Morellato [org.], História Natural da Serra do Japi: Ecologia e Preservação de uma Área Florestal no Sudeste do Brazil, pp. 212–236. Campinas, Editora UNICAMP) and is very hard to capture (pers. obs.). Thus, the snake preyed on by the *B. jararacussu* most likely struggled after the first hold and was bitten several times by its predator, which would explain the multiple hemorrhage marks.

We thank L. A. Kobata for the field observations, I. Sazima for critical reading, and the CNPq for financial support to OAVM. This note is part of the Project "História Natural, Ecologia e Evolução de Vertebrados Brasileiros" funded by the FAPESP (grant 00/12339-5).

CANDOIA ASPERA (Pacific Ground Boa). **DIET**. The diet of *Candoia aspera* from New Guinea is not well documented. Like other ground-dwelling boids, it has been assumed their prey includes frogs, small mammals, and lizards (O'Shea 1996. A Guide to the Snakes of Papua New Guinea. Independent Group Pty Ltd., Singapore. 239 pp.). On 17 March 1996, while hiking between the villages of Haia and Wabo, in Southern Highlands Province, Papua New Guinea (~ 145°03'E and 6°49'S), I found an adult *C. aspera* (SVL 75 cm) with a relatively large (600 g; ca. 50% of mass of the snake) and partially ingested White-bellied Forest Rat (*Melomys leucogaster*). At this time the snake did not attempt to flee or disgorge the rat, but moved slowly and just off the trail. After it had all but the tail tip swallowed, it again began to move slowly away from the trail. Ingestion was completed at 16 min from onset of the observation. Following ingestion, the snake did not appear to not be disturbed by my presence; it moved 5–6 m off the trail and curled up at the base of a large tree in a root buttress. The relatively large size of this rat may have been the reason why the snake did not move quickly or attempt to disgorge the prey item.

CLONOPHIS KIRTLANDII (Kirtland's Snake). **REPRODUCTION**. Published literature on the reproductive biology of *Clonophis kirtlandii* is scant throughout its range (Conant 1943. Amer. Midl. Nat. 29:313–341; Ernst and Barbour 1989. Snakes of Eastern North America. George Mason University Press, Fairfax, Virginia. 282 pp.; Fitch 1970. Univ. Kansas Mus. Nat. Hist. Misc. Pub. 52:1–247; Minton 2001. The Amphibians and Reptiles of Indiana. Indiana Academy of Sciences, Indianapolis. 404 pp.; Powell and Parmerlee 1991. Bull. Chicago Herpetol. Soc. 26:32; Smith 1961. Illinois Nat. Hist. Surv. Bull. 28:1–298; Tucker 1976. J. Herpetol. 10:53–54; Wright and Wright 1957. Handbook of Snakes of the United States and Canada. Cornell University Press, Ithaca, New York. 1105 pp.). Life history data are also scarce or unpublished on northeastern Illinois populations of this Illinois state-threatened species

On 27 June 2002, at 1430 h, a female *C. kirtlandii* (SVL 390 mm, 40 g) was collected while partially concealed in a crayfish burrow under a plastic bottle at a preserve in eastern Will Co., Illinois. It was retained in captivity for potential reproductive data and housed in a fiberglass cage 30 x 16 x 20 cm on a paper towel substrate with water *ad libitum* and a ceramic shelter. The cage was subject to natural conditions (e.g., kept outdoors on a screened porch). The snake was offered 1–10 earthworms (*Lumbricus* sp.) once per week, and consumed all that were offered. It was allowed sufficient time to defecate (5–12 days) and then measured. It shed on 19 July and weighed 48 g on 10 August, a mass it maintained for 15 days. Between 25 August and 2 September, the snake weighed 2.5 g less before feeding on 2 September. After sufficient time for defecation elapsed, its mass on 6 September was 45.5 g.

On 8 September, between 1000 h and 1400h, the female pro-

duced 10 neonates and one undeveloped egg. Her post-partum mass was 22 g, and total litter mass was 12 g; afterbirth and undeveloped egg mass totaled 11.5 g. Combined mass (neonates, afterbirth, and undeveloped egg) was 23.5 g. The SVL and mass ranges of the neonates (4 males, 6 females) were 72–118 mm and 0.5–1.5 g. One neonate (female, SVL 85 mm, 0.5 g) died 9 September, and exhibited a prolapsed liver that protruded from the umbilical region. It was preserved in 95% ethanol and deposited in the herpetology collection of the Illinois Natural History Survey (INHS 18566). The smallest neonate (male) had a spinal kink in the posterior one-third of the body, but maintained an activity level similar to that of its littermates. The female and nine remaining neonates were released at the capture site on 13 September 2002.

We thank the Illinois Department of Natural Resources (Joe Kath) for permits. Alan Resetar made helpful comments on the manuscript.

CONOPSIS LINEATA (Lined Tolucan Ground Snake) and ***LEPTODEIRA MACULATA*** (Southwestern Cat-eyed Snake). **ENDOPARASITES.** *Conopsis lineata* ranges widely across the central Mexican Plateau (Flores Villela and Gerez 1994. Biodiversidad y Conservacíon en México: Vertebrados, Vegetación y Uso del Suelo. Comision Nacional para el Conocimiento y uso de la Biodiversidad y Universidad Nacional Autónoma de México, Ciudad Universitaria, México, D.F. 439 pp.); *Leptodeira maculata* occurs along the Mexican Pacific Coast from Sinaloa to Guerrero (Flores Villela and Gerez, *op. cit.*). There are, to our knowledge, no reports of endoparasites from *C. lineata* and *L. maculata*. The purpose of this note is to report the presence of larval spiny-headed worms (acanthocephalans) in both snake species. Sixty-two *C. lineata* and 46 *L. maculata* were examined from the Natural History Museum of Los Angeles County, Los Angeles (LACM). A mid-ventral incision was made in the body wall, and organ surfaces and mesenteries in the posterior portion of the body cavity were visually checked for helminths. One *C. lineata* from Hidalgo (LACM 127102), collected 5 January 1978 and one *L. maculata* from Sinaloa (LACM 7243) collected 21 July 1960 contained oblong whitish bodies, ca. 1 x 3 mm. On microscopic examination they proved to be oligacanthorhynchid acanthocephalan cystacanths. Prevalence of infection (infected snake/sample examined x 100) was 2% for both *C. lineata* and *L. maculata*. The specimens were deposited in the United States National Parasite Collection, Beltsville, Maryland as USNPC 91935 for *C. lineata* and USNPC 91978 for *L. maculata*.

Oligacanthorhynchid cystacanths have been previously found in Mexico (Baja California 1/8 [13%], Chihuahua 2/2 [100%], Coahuila 5/9 [56%], Durango 2/2 [100%], Sinaloa 2/6 [33%], and Sonora 9/26 [35%]) in the colubrid snake, *Rhinocheilus lecontei* (Goldberg et al. 1998. J. Helminthol. Soc. Washington 65:262–265). Acanthocephalans require at least two hosts in the life cycle; arthropods are the usual intermediate hosts in which the infective stage, the cystacanth, develops (Nickol 1985. *In* Crompton and Nickol [eds.], Biology of the Acanthocephala, pp. 307–346. Cambridge University Press, Cambridge, UK). When eaten by a definitive host, the cystacanth excysts and develops to maturity somewhere in the digestive tract of the definitive host. Paratenic hosts (transport hosts) are common; the cystacanth enters with prey and excysts, but if the host is inappropriate, it migrates from the intestine into the body cavity and again encysts. *Conopsis lineata* is known to eat insects (Sánchez-Herrera 1980. Bull. Maryland Herpetol. Soc. 16:9–18). Snakes of the genus *Leptodeira* eat lizards and anurans (Duellman 1958. Bull. Am. Mus. Nat. Hist. 114:1–152) and infection is most likely secondary, i.e., re-encystment of cystacanths originally in lizards or anurans. Infected snakes likely serve as paratenic hosts. *Conopsis lineata* and *L. maculata* are new host records for oligacanthorhynchid acanthocephalan cystacanths. Hidalgo is a new locality record.

We thank David A. Kizirian (Natural History Museum of Los Angeles County) for permission to examine *C. lineata* and *L. maculata*.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu), and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail:cxb13@psu.edu).

CONOPSIS LINEATA (Lined Tolucan Ground Snake). **REPRODUCTION.** *Conopsis lineata* ranges widely across the central Mexican Plateau (Uribe-Peña et al. 1999. Anfibios y Reptiles de las Serranías del Distrito Federal, México. Cuadernos 32, Instituto de Biología, Universidad Nacional Autónoma de México, México, D.F. 119 pp.). Information that *C. lineata* is viviparous was reported by Greer (1966. Copeia 1966:371–373). Four *C. lineata* in the Museum of Comparative Zoology from Hidalgo (no dates) contained 2, 3, 3, 3 embryos and two collected from Veracruz in January contained 3 and 5 embryos (Greer, *op. cit.*).

A histological examination was performed on gonadal material from 37 *C. lineata* in the herpetology collection of the Natural History Museum of Los Angeles County (LACM). Specimens were from the Mexican states of Hidalgo, Michoacán, Oaxaca, Puebla, Tlaxcala, and Veracruz. The study was limited to adults. A total of 18 females, mean snout–vent length, SVL = 212 mm ± 30 SD, range 176-258 mm; 17 males, SVL = 191 mm ± 26 SD, range = 150–234 mm were examined. The left testis or left ovary was removed, dehydrated in ethanol and embedded in paraffin. Histological sections were cut at 5 µm and stained with Harris' hematoxylin followed by eosin counterstain. Enlarged ovarian follicles or oviductal eggs were counted but were not examined histologically.

The males exhibited the following testicular conditions: January (1) recrudescent (renewal of germinal epithelium); April (1) spermiogenesis (sperm formation); July (3) spermiogenesis; August (9) 7 spermiogenesis, 2 early regression (germinal epithelium exhausted, small amounts of sperm remain); September (2) spermiogenesis; December (1) advanced recrudescence. The smallest reproductively active male (spermiogenesis) measured 150 mm SVL (LACM 59117). Females exhibited the following ovarian conditions: January (2) 4 enlarged follicles > 6 mm length (LACM

127104) SVL 206 mm, Puebla; 3 oviductal eggs (LACM 121891) SVL 188 mm, Veracruz; 30 June–1 July (1) 6 well-developed embryos (LACM 130664) SVL 257 mm, Oaxaca; August (15) 11 no yolk deposition, 4 early yolk deposition. The smallest reproductively active female (early yolk deposition in progress) measured 176 mm SVL (LACM 69078). The mean litter size for the six litters from Greer (*op. cit.*) and the three litters from LACM (3, 4, 6) is 3.6 ± 1.2 SD, range = 2–6.

The lack of monthly samples does not allow a description of the seasonal testicular cycle, however the presence of one April spermiogenic male, spermiogenic males from July–September and one male in advanced recrudescence from December and January suggests a prolonged period of sperm production. Four of 15 August females in early yolk deposition suggests that females commence reproductive activity during this month. The six embryos from LACM 130664 is a new maximum litter size for *C. lineata*. I thank D. Kizirian (Natural History Museum of Los Angeles County) for permission to examine *C. lineata*.

CROTALUS CATALINENSIS (Santa Catalina Island Rattleless Rattlesnake). **DIET**. *Crotalus catalinensis* is endemic to Isla de Santa Catalina (25°39'N, 110°49'W), Baja California Sur in the Gulf of California (Beaman and Wong 2001. Cat. Am. Amphib. Rept. 733.1–733.4), 24 km from the peninsular coast. The loss of the rattle has been hypothesized to increase hunting efficiency (Greene 1997. Snakes: The Evolution of Mystery in Nature. Univ. California Press, Berkeley. 351 pp.; Rubio 1998. Rattlesnake: Portrait of a Predator. Smithsonian Inst. Press, Washington. 272 pp.; Grismer 2002. Amphibians and Reptiles of Baja California, Including Its Pacific Islands and the Islands in the Sea of Cortés, University of California Press, Berkeley, California, 409 pp.). Because of its propensity to climb on shrubs, it has been speculated that this rattlesnake preys mainly on birds (Grismer 2002, *op. cit.*).

As part of a broad ecological project on *C. catalinensis*, during two visits to the island 16 adult individuals (10 males, 6 females) and 1 neonate were palped in order to obtain stomach contents. Only two of the snakes (11.7%) presented food items, and both were identified as the endemic rodent species of the island, Santa Catalina Deer Mouse, *Peromyscus slevini* (Hall 1981. The Mammals of North America, John Wiley and Sons, New York. Vol II. 1181 pp.).

On 25 August 2002, at 1900 h, an adult male *C. catalinensis* (SVL 510 mm, TL 554 mm, mass 110 g, live mass with prey item) was found coiled under an Iron Tree (*Ebenopsis confinis*) on the west part of the island. The stomach contents were obtained by forced regurgitation and a partially digested *P. slevini* (3.5 g), swallowed head-first was found.

On 18 October 2002, at 2135 h, on the south part of the island an adult male *C. catalinensis* (SVL 572 mm, TL 621 mm, mass 126 g, live mass with prey items) was found coiled on an outer branch of a Red Elephant Tree (*Bursera hindsiana*) at a height of 0.6 m from the floor. Two *P. slevini* were obtained by forced regurgitation. The first food item was a minimally digested male (TL 155 mm, T 87 mm, HF 19 mm, 9 g). The second item (1.5 g) was considerably more decomposed (e.g., two thirds of the body). Both mice were swallowed headfirst.

We observed many *P. slevini* climbing on shrubs, and perhaps this could be another reason for the arboreal hunting habits of *C. catalinensis*, in addition to searching for bird prey.

We thank Tosha Comendant and Sergio Avila for support and useful comments on earlier versions of this manuscript.

CROTALUS HORRIDUS (Timber Rattlesnake). **ARBOREALITY, DIET.** Although rattlesnakes are typically terrestrial animals, recent studies have demonstrated that arboreal activity is a regular aspect of timber rattlesnake behavior (see Coupe 2001. Herpetol. Rev. 83–85). Possible motives ascribed to such activity include thermoregulation, ecdysis, courtship, and foraging. Although arboreal animals such as squirrels and song birds have been reported in timber rattlesnake diets, arboreal foraging has not been confirmed. Here, we report on an instance of arboreal predation by a timber rattlesnake on a male Yellow-bellied Sapsucker (*Sphyrapicus varius*). The observation was made by Steven and Lucille Mitchell during the summer of 1981. Details were obtained by an interview with Mrs. Mitchell in 2001. The incident occurred on a clear, warm mid-summer afternoon (1600

FIG. 1. Timber rattlesnake holding male sapsucker.

h). Steven, at that time 5 years old, heard a bird calling loudly from a large American Elm tree in their back yard (IOWA: Allamakee Co: Lansing Township: T100N, R4W, Sec 34, NW 1/4 of SE 1/4). Looking up he saw the bird moving about and calling loudly in front of the snake on a branch ca. 4.5– 6 m above ground. While he watched, the snake struck and held the bird, both falling from the branch onto another branch ca. 1–1.5 m above ground. He ran into the house and Mrs. Mitchell returned with him, took photos (Fig. 1) and killed the snake. No measurements were taken on the snake. Mrs. Mitchell states that the bird was no longer moving when she arrived.

CROTALUS HORRIDUS (Timber Rattlesnake). **ARBOREALITY, COURTSHIP**. Arboreal courtship in timber rattlesnakes has only been reported once (Coupe 2001. Herpetol. Rev. 32:83–85). Here we report a second instance of arboreal courtship, from a site in Crawford County, Wisconsin. On 16 Aug 2001 a radio-implanted male rattlesnake (100.5 cm SVL, 7.5 cm tail, 966 g) was observed coiled together on the ground with a large pre-shed female (98.0 cm SVL, 6.0 cm tail, 835 g). Four days later (20 Aug) the male was observed 1 m above ground coiled together with the same female. They were observed together in the same posture and location on each of the next five days. On 26 Aug the male had moved to the ground 5 m from the female, who remained in the tree. They were observed in these same separate locations through 28 Aug. On the morning of 29 Aug the male had moved to 2 m from the female. On the morning of 30 Aug he was observed 2 m up in a sapling 1.75 m from the female who was 1.5 m above ground at the same location she had been since 20 Aug. At 1500 h that afternoon both snakes were in the same locations. At 1800 h the male had joined the female again (Fig. 1) where they remained together through 1550 h on 1 Sept.

Submitted by **ARMUND D. BARTZ**, 64406 Mule Hollow Road, DeSoto, Wisconsin 54624, USA (e-mail: bartza@mailO1.dnr.state.wi.us), and **RICHARD A. SAJDAK**, 4 Callingham Road, Pittsford, New York 14534, USA (e-mail: rsajdak@frontiernet.com).

CROTALUS HORRIDUS (Timber Rattlesnake). **DEFENSE AND BLACK BEAR DEATH.** There has been no record, to the best of our knowledge, of a Timber Rattlesnake (*Crotalus horridus*) killing a Black Bear (*Ursus americanus*) in defense. On 9 June 2000 personnel of the Cooperative Alleghany Bear Study confirmed the mortality of a 4-month-old female *U. americanus* on the George Washington and Jefferson National Forest in western Virginia. It was found in a mixed hardwood-pine stand lying on its left side in a fetal position with its chin positioned upward. The cub (3.3 kg) was from a litter of four (2 males: 2 females), and had been radio-collared in the den on 15 March 2000.

A necropsy performed at the Virginia-Maryland Regional College of Veterinary Medicine indicated swelling of the proximal caudomedial aspect of the left hind limb that was associated with a locally extensive area of demarcated and discolored skin (necrosis) with extensive subcutaneous edema that extended into the underlying muscle. The distance between the prominent punctures was 11.35 mm (Fig.1). There was moderate post-mortem autolysis of the carcass, including all organs. Gross pathological findings were consistent with a venomous snakebite (Duncan and Shoieb 2001. Necropsy Report 2001-303. Virginia Maryland Regional College of Veterinary Medicine, Virginia Polytechnic Institute and State University, Blacksburg).

In western Virginia, venomous snakes include the Copperhead (*Agkistrodon contortrix*) and Timber Rattlesnake (*Crotalus horridus*) (Mitchell 1994. Smithsonian Institution Press, Washington). Identification of the snake species responsible in this incident by the bite pattern is difficult because pitvipers have fangs that rotate not only forward but also laterally, leaving the bite wounds up to 112% wider than the resting inter-fang distance (Zamudio et al. 2000. Toxicon 38:723–728). Given the small distance of the fang width (11.35 mm), both snake species were con-

FIG. 1. Male and female rattlesnakes coiled together at 1920 h on 30 Aug 2001. Male's head is resting on the female's head.

FIG. 1. Snakebite pattern found on the inner thigh of the left hind leg of a 3.3 kg black bear (*Ursus americanus*) cub in Rockingham County, Virginia, 9 June 2000.

sidered possible candidates for the bite. The inter-dental space between fangs was measured in two archival skull specimens derived from *A. contortrix* (TL 81 cm) and *C. horridus* (TL 121 cm) that were prepared and mounted in an open-mouth, extended-fang position. The inter-dental spaces were 7 mm and 12 mm, respectively. Mitchell (*op. cit.*) reported that both *A. contortrix* and *C. horridus* are found in mixed hardwood-pine forests, which characterizes the habitat where the dead bear was found. Based on the extent of localized tissue damage and documentation of punctures with an 11.35 mm intervening space, a bite from *C. horridus* was considered more likely. The venom of *C. horridus* is more toxic and can cause more extensive tissue damage; however, due to the size of the cub it is possible that a bite from *A. contortrix* delivered the fatal bite. Even though we cannot definitively determine which snake species caused this mortality, the observation remains unique in reported cases of mortality in juvenile *U. americanus*.

This project was funded by Virginia Department of Game and Inland Fisheries, United States Forest Service, United States Geological Survey – Biological Resources Division, Virginia Polytechnic Institute and State University, Virginia Bear Hunters Association, Virginia Houndsmen and Sporting Dog Association, and Safari Club International. We thank N. Rein for the provided photos and the detailed field notes that supported this observation. I would also like to thank K. Ernst, H. Greene, J. Mitchell, A. Savitzky, and K. Zamudio for their input on snakebite identification.

CROTALUS LEPIDUS KLAUBERI (Banded Rock Rattlesnake). **MORPHOLOGY**. Klauber (1972. Rattlesnakes. Their Habits, Life Histories, and Influence on Mankind. Univ. Califonia Press, Berkeley, California. 740 pp.) reported the congenital absence of rattles in three species of rattlesnakes, *Crotalus cerastes, C. horridus,* and *C. pricei*. Subsequently, congenital absence of the rattle has been reported for *C. atrox* (Painter et al. 1999. Herpetol. Rev. 30:44; Holycross 2000. Herpetol. Rev. 31:177–178) and *C. viridis* (Holycross 2000. Herpetol. Rev. 31:177). Herein we report a rattleless female *Crotalus lepidus klauberi* with an abruptly tapered tail that was collected 28 Sept 2002 in the Animas Mountains, Hidalgo County, New Mexico, USA. Of 165 specimens (male and female) examined in the Animas (N = 81), Peloncillo (N = 60), and Chiricahua (N = 24) mountains (1991–2002), this was the only rattleless specimen. The rattleless specimen had 13 subcaudals, below the range observed (16–22, mean = 18.6 ± 0.2 SE) for 56 females for which we have data from these mountain ranges. The absence of scarring or injury suggests the condition

FIG. 1. Congenital lack of rattle in an adult female *Crotalus lepidus klauberi*.

might be congenital. The tail of the snake was photographed prior to release (Fig. 1).

CROTALUS LEPIDUS (Rock Rattlesnake). **DIET**. *Crotalus lepidus* is a widely distributed rattlesnake that occurs from southeastern Arizona, southern New Mexico, and southwestern Texas through most of the Sierra Madre Occidental and northern portion of the Mexican Plateau, and the northern portion of the Sierra Madre Oriental (Campbell and Lamar 1989. The Venomous Reptiles of Latin America. Comstock Publ. Assoc., Ithaca, New York. 425 pp.). Holycross et al. (2002. J. Herpetol. 36:589–597) summarized the published dietary records for this species. Most of these dietary records were obtained from snakes north of Mexico. Only one prey item has been recorded for the endemic Mexican subspecies *C. l. morulus*. Klauber (1972. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. 2 Vols., 2nd ed. Univ. California Press, Berkeley. 1533 pp.) reported one specimen of *C. l. morulus* contained lizard scales (unidentified species). Herein we provide dietary records for *C. l. lepidus* and *C. l. morulus* from Nuevo León, Mexico.

In July 2001, while conducting a herpetofaunal inventory of the Sierra San Antonio Peña Nevada in the municipality of Zaragoza, Nuevo Leon, we collected three individuals of *C. l. morulus*. They were found in an oak-agave forest at ca. 2700 m elevation. Mass of all animals was taken immediately after capture but no length measurements were made. After defecation in the lab, fecal remains were analyzed. The fecal material of one adult male *C. l. morulus* (UANL 5801, 118 g) contained scales of the anguid lizard *Barisia imbricata ciliaris*. Bryson et al. (2003. Herpetol. Rev.

34:65–66) found *B. i. ciliaris* remains in the fecal matter of a *C. pricei miquihuanas* from Coahuila, Mexico. Fecal matter from a juvenile female *C. l. morulus* (UANL 5802, 19.7 g) contained *Eumeces brevirostris pineus* scales and bone fragments. Fecal matter from a juvenile male (UANL 5804, 22.9 g) contained *Sceloporus grammicus disparilis* scales. Gloyd and Smith (1942. Bull. Chicago Acad. Sci. 6:231–235) documented *S. g. disparilis* (reported as *S. microlepidotus disparilis*) as a prey item of *C. l. lepidus* from the Sierra del Carmen in Coahuila, México.

On 22 August 2002 we found a juvenile male *C. l. lepidus* (UANL 6181, 354 mm TL) dead on the road west of San Isidro, Municipio Santiago, Nuevo León, Mexico. The snake had a juvenile *Sceloporus minor* in its mouth, and both it and lizard were badly crushed. We were thus unable to determine if the snake had been run over while consuming the lizard that it had killed, or if the snake had been scavenging an already dead-on-road lizard. DeVault and Krochmal (2002. Herpetologica 58:429–436) reviewed reports of scavenging in snakes and reported that 31% of unprovoked scavenging incidents from field observations were by rattlesnakes. The road on which the *C. l. lepidus* was found runs through a canyon (ca. 1600 m elevation at the base) characterized by steep limestone walls covered with agave, sotol, and scrub oak. On 3 October 2002 we found a large male *C. l. lepidus* (UANL 6199, 740 mm TL) dead on a dirt road near Laguna de Sanchez, Municipio Santiago, Nuevo León, Mexico. Dissection of the specimen revealed that it had consumed a large *Sceloporus torquatus binocularis* (116 mm SVL, 128 mm tail length).

Submitted by **DAVID LAZCANO** (e-mail: dvlazcano@hotmail.com), **JAVIER BANDA LEAL**, Gamaliel Castañeda G., Cristina García de la Peña, Laboratorio de Herpetología, Universidad Autónoma de Nuevo León, Apartado Postal - 513, San Nicolas de los Garza, Nuevo León, C.P. 66450, México, and **ROBERT W. BRYSON, JR.**, Department of Biology, Sul Ross State University, Alpine, Texas 79832, USA.

CROTALUS MOLOSSUS MOLOSSUS (Black-tailed Rattlesnake). **MALE-MALE FIGHTING**. Observations of male-male fighting in free-ranging rattlesnakes are rarely published. Male-male fighting has not been published for *Crotalus m. molossus*. Here we describe a case of male-male fighting at Parker Creek, Sierra Ancha Mts., Gila Co., Arizona, USA.

On 1 August 1999 at 1100 h, we found a pair of *C. m. molossus* entangled with each other in the water of a running creek. Both had about three-fourths of their bodies immersed in the water. They had apparently fallen into the creek, as they were at the bottom of a steep dirt slope. The snakes were about the same body length (ca. 140 cm SVL). One was considerably paler and somewhat smaller, and had a less contrasting black and yellow dorsal color. The snakes were wrestling, at times twisting together the full lengths of their bodies. They also raised their heads above the ground to their full extents. Their movements appeared sluggish and uncoordinated, possibly because of the immersion in water, which was considerably cooler than the air. The fight moved out of the water ca. 1 min. after we began our observations (Fig. 1). Both snakes seemed oblivious to 8 students observing them from a distance of 4 m. The interaction ended ca. 45 min. later, with the duller colored, smaller individual retreating.

FIG. 1. Male combat in *Crotalus molossus*.

Although male fighting in snakes commonly occurs in the presence of a female (e.g., Schuett 1997. Anim. Behav. 54:213–224), no other snakes were seen in the area. However, the area was not intentionally searched for other snakes.

CROTALUS RAVUS (Mexican Pygmy Rattlesnake). **DIET**. The feeding habits of *Crotalus (= Sistrurus) ravus* have not been thoroughly documented. Uribe-Peña et al. (1999. Anfibios y Reptiles de las Serranias del Distrito Federal, México. Cuadernos, IB UNAM 32:82) refer to a paper by Sánchez-Herrera (1980. Bull. Maryland Herpetol. Soc. 16:9–18) indicating that this species consumes vertebrates, such as lizards (*Sceloporus grammicus* and *Sceloporus megalepidurus*), mammals (*Mus musculus* and *Microtus mexicanus*), and insects. Nevertheless, data on the diet of *C. ravus* are not contained in Sánchez-Herrera (*op. cit.*). In fact, *S. megalepidurus* does not occur in the mountains surrounding Distrito Federal (Smith 1939. Zool. Ser. Field. Mus. Nat. Hist. 26:204; Sites et al. 1992. Bull. Amer. Mus. Nat. Hist. 213:45). The reference cited by Uribe-Peña et al. (1999) is from the unpublished bachelors thesis of O. Sánchez-Herrera (1980. Herpetofauna de Tlaxcala. Fac. de Ciencias, UNAM, México, 155 pp.).

Here we report on a juvenile female *C. ravus* collected on 17 August 2002 in the vicinity of Mexico City, in the mountains surrounding the Valley of Mexico (Huixquilucan, Zacamulpa, State of Mexico). This specimen was deposited in the Museo de Zoologia, Facultad de Ciencias (MZFC 14287). Measurements were obtained before dissection (SVL 167 mm, TL = 186 mm, HL

= 15.1 mm, and HW = 10 mm). Upon dissection, a partially digested adult *S. grammicus* and a specimen of the Order Hemiptera (possibly a member of Pentatomidae, head and wings) were in the stomach. O. Sánchez-Herrera (*op. cit.*) refers to four specimens of *C. ravus* collected by him in the Mexican State of Tlaxcala. He found the lizards and mice cited above, and also noted that one small individual (TL 216 mm) contained a large (27.3 x 10.4 mm) cricket (Orthoptera, Gryllidae). Our observations confirm that, in addition to lizards and small mammals, certain insects constitute a portion of the diet of juvenile *C. ravus*.

We thank Enrique González-Soriano for his help determining the hemipteran.

Submitted by **ALBERTO MENDOZA-HERNÁNDEZ, OSCAR FLORES-VILLELA, ESTRELLA MOCIÑO-DELOYA,** and **OSCAR SÁNCHEZ-HERRERA**, Museo de Zoología, Facultad de Ciencias, UNAM, A.P. 70-399 Mexico D.F. 04510, Mexico.

DABOIA RUSSELII RUSSELII (Sri Lankan Russell's Viper). **LARGE PREY**. *Daboia russelii* is a highly venomous, terrestrial viperid that preys on a variety of vertebrates and invertebrates, including rodents (Wüster 1998. Hamadryad 23:33–40). The Sri Lankan population, previously known as *Daboia russelii pulchella*, recently was synonymized with *D. russelii russelii* (Wüster et al. 1992. Biol. J. Linn. Soc. 47:97–113; Rage and Toriba 1993 *In* Golay et al. [eds.], Endoglyphs and Other Major Venomous Snakes of the World: A Checklist, pp. 267–688. Azemiops, Geneva, Switzerland; Wüster 1998, *op. cit.*)

A preserved (unaccessioned) juvenile *D. r. russelii*, from the vicinity of Nikaweratiya, North Western Province, ca. 90 km NNE of Colombo, in the care of one of us (SAMK), was examined by MOS and ADS for stomach contents. The specimen had fed just prior to being killed and was found to contain a single, murid rodent (House Mouse; *Mus musculus*) of considerable size in relation to the snake (Fig. 1). The snake measured 180 mm SVL (210 mm TL) and was 21 g. The mouse measured 66 mm SVL (109 mm TL) and was13.5 g. Rodents often constitute a 'Type III' prey item, which is typical for viperids (Cundall and Greene 2000. *In* Schwenk [ed.], Feeding: Form, Function, and Evolution in Tetrapod Vertebrates, pp. 293–333. Academic Press, San Diego, California), the prey/predator body length ratio of 0.37 and mass ratio of ca. 0.64 are considerable, even when taking into consideration the presence of preservative fluid in both specimens.

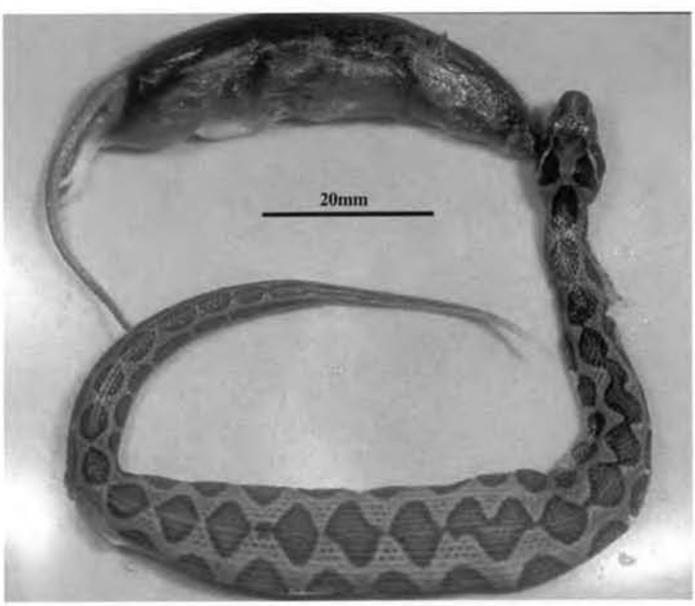

FIG. 1. A juvenile *Daboia russelii russelii* and the prey item (*Mus musculus*) it consumed; the relative predator/prey mass of this food item was 0.64.

We thank C. Wijesundara of the Faculty of Science, Peradeniya University, Sri Lanka, for the identification of the mouse, and YAP Films and Animal Planet for funding and support of the project 'O'Shea's Big Adventure Series 3': "Venom" in Sri Lanka.

Submitted by **MARK O'SHEA**, School of Applied Sciences, University of Wolverhampton, Wolverhampton, WV1 1SB, England (e-mail: oshea@snakemos.demon.co.uk), **ANSLEM DE SILVA**, Faculty of Medicine, University of Peradeniya, Peradeniya, Sri Lanka (e-mail: kalds@sltnet.lk), and **S. A. M. KULARATNE**, Faculty of Medicine, University of Peradeniya, Peradeniya, Sri Lanka (e-mail: samkul@sltnet.lk).

DIADOPHIS PUNCTATUS (Ring-necked Snake). **ENDOPARASITES.** Twenty-four *Diadophis punctatus* (Colubridae) from the herpetology collection of the University of Arizona (UAZ; all specimens from Arizona, USA) were examined for endoparasites. A mid-ventral incision was made in the body wall and organ surfaces and mesenteries in the posterior portion of the body cavity were visually checked for helminths. Three *D. punctatus* contained oblong whitish bodies measuring ca. 1 x 3 mm; upon microscopic examination they were proved to be larvae (cystacanths) of Spiny-headed Worms (Acanthocephala, Oligacanthorhynchidae) (UAZ 36293, Santa Cruz County) (N = 5), (UAZ 36293, Pinal County) (N = 6), and (UAZ 37837, Santa Cruz County) (N = 1). Prevalence of infection (infected snake/sample examined x 100) was 13%. The helminths were deposited in the United States National Parasite Collection. Beltsville, Maryland (USNPC 92282).

The occurence of oligacanthorhynchid cystacanths in North American reptiles is summarized by Bolette (1997. Southwest. Nat. 42:232–236), who states that snakes are paratenic (transport) hosts. Additional cystacanths of rattlesnakes were listed by Goldberg and Bursey (1999. Herpetol. Rev. 30:44-45; 2000. Herpetol. Rev. 31:104). Only one other colubrid snake species, *Rhinocheilus lecontei* from Arizona, has been reported to harbor cystacanths (Goldberg et al. 1998. J. Helminthol. Soc. Washington 65:262–285). *Diadophis punctatus* represents a new host record for oligacanthorhynchid cystacanths.

We thank George Bradley (University of Arizona) for permission to examine *D. punctatus*.

BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

DINODON RUFOZONATUM RUFOZONATUM (Red Banded Snake). **INSECTIVORY**. The genus *Dinodon* consists of about eight species that occur in an area that extends from eastern Himalayas, eastward through Burma, southern China and northern Indo-China to Japan.

Dinodon r. rufozonatum is the only member of this genus that naturally occurs in Taiwan (Lue et al. 2002. The Transition World—Guidebook of Amphibians and Reptiles of Taiwan. SWAN, Taipei. pp. 182–183 pp. [in Chinese]). This nocturnal species is fairly common in Taiwan, where it inhabits areas not far from water in a wide variety of habitats (Tu and Lin 1999. Nature Conservation Quarterly Issue 28:26–29 [in Chinese]; Kuntz 1963. Snakes of Taiwan. Quart. J. Taiwan Mus. 16:42–44). Known food items include frogs, loaches, small snakes, skinks, and hatchling birds (Kuntz, *op. cit.*; Lee and Lue 1996. Biol. Bull. NTNU 31:119–124 [in Chinese]; Lee and Lue 1996. J. Taiwan Mus. 49[2]:137–138; Lin et al. 1995. Newsletter of Wildlifers. 3:19–21 [in Chinese]; J. Mao, unpubl. data).

On the 14 July 2002 at 2249 h, a DOR adult *Dinodon r. rufozonatum* was found alongside a road at 23°26.995'N, 120°28.102'E, near Santzepu, Shuisan District, Chiayi County, 50 m elev. Dissection revealed that the snake was infested by an internal parasite and the stomach contained a hard, dark-colored object. The stomach was removed and was found to contain some grass blades, a small stone, and a 13.4 mm long beetle (*Cosmopolites sodidus*; Fig.1). Because the insect was virtually undigested and very little other material was found in the stomach, we believe that the snake preyed on the beetle.

We believe this is the first report of *D. r. rufozonatum* feeding on an coleopteran insect.

FIG. 1. A beetle, *Cosmopolites sodidus*, after it was removed from the stomach of the *Dinodon r. rufozonatum*.

Submitted by **GERRUT NORVAL,** Global Village Education Center. No. 436, Chong-San Rd., Chiayi City 600, Taiwan, R.O.C. (e-mail: gerrutnorval507@yahoo.com), and **JEAN-JAY MAO,** Fachbereich VI- Biogeographie, Universität Trier, D-54286 Trier, Deutschland.

ELAPHE BAIRDI (Baird's Rat Snake). **PREDATION**. Like many rat snakes, *Elaphe bairdi* is a generalist predator with a cosmopolitan diet known to comprise lizards, rodents, birds and their eggs, and bats (Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History, Univ. Texas Press, Austin. 544 pp.). It is a powerful constrictor and a good climber, easily able to negotiate the rocky, limestone cliffs and outcrops of its preferred habitat. This note documents an incident of diurnal predation of a small avian by this snake.

On 18 May 2000, between 1245 and 1330 h, I witnessed a large *E. bairdi* methodically take several cliff swallows *(Hirundo pyrrhonota)* from their nests under a limestone ledge in Real County, Texas, USA. The locality is immediately adjacent to the Frio River and within the H. E. Butts Foundation Camp. This location is on Texas State Highway 83 ca. 26 km N of Leaky, Texas, USA.

The sky was clear, the air temperature ca. 37.0°C, and the wind calm. Humidity was relatively high, ca. 75%. The barometric pressure was rising. The habitat surrounding the river in this location comprises a series of Cretaceous limestone bluffs and outcrops varying in height from 20 to nearly 200 m. The dominant vegetation is *Juniperus ashei*, *Quercus sinuata*, *Sophora secundiflora*, and *Juglans major* on the elevated terrain, with *Platanus occidentalis* and *Taxodium distichum* along the river bottom.

A limestone cliff on the south side of the river, near a vehicle pull out, rises precipitously at nearly 90° for ca. 30 m at which point an overhanging shelf of ca. 1 m forms. This shelf, which rises outward, away from the vertical surface at ca. 50°, offers substantial overhead protection from the effects of sun and weather for a considerable number of gourd-shaped cliff swallow nests made of mud. The nests, 36 of which appeared to be in use, were built on the cliff where the vertical surface joins the overhang at a 90° angle. Many adult swallows were observed flying in the immediate vicinity of the nests. In fact, it was their loud alarm calls that drew my attention to the nest site.

After observing the site for several minutes without detecting a cause for the birds' alarm, my attention was drawn to what at first appeared to be a dark root growing from a crack in the limestone. Examining the "root" with binoculars revealed a large *E. bairdi*. The snake was draped over the cliff and had curled its body underneath the overhang in an attempt to attack the cliff swallows.

Two thirds of the snake's body was completely under the overhang, the posterior one third remaining on the slanting, upper surface of the cliff where the tail had obtained purchase on some surface irregularity in the rough limestone. Under the overhang, the snake had looped a coil of its mid-section into the enlarged opening of an obviously empty swallow nest. From this forward anchor point, it was using the anterior 40 cm or so of its body to methodically search all nests within its reach. Each time its head entered a nest it stayed for several minutes. While it was impossible to observe any actual predation, it was quite obvious that the snake was eating the contents of the nests for periodically it would swallow an object that could easily be seen as the snake's muscular contractions passed it down the esophagus. The objects swallowed were undoubtedly young birds. The snake did not constrict this prey in the typical manner of rat snakes, as juvenile cliff swallows are small and probably offered little resistance to the snake's attack.

In the 45 minutes that it was under observation the snake searched six nests, consuming the contents of each. Nest contents varied, but at least two birds were swallowed from each nest and, in one case, as many as four.

After searching the last nest, and being able to reach no others, the snake withdrew its body from the empty nest and swung down,

supported only by its tail. The mid-section was visibly swollen with prey, but this condition did not appear to hinder mobility. The snake slowly elevated its body above the overhang. Once on top, it crawled higher on the cliff to disappear under a large sotol plant *(Dasylirion texanum)*.

While the snake was present, the swallows maintained an erratic flight pattern in front of the cliff, giving alarm calls. They did not attempt to attack the snake. Only when the snake disappeared from view did their calls stop.

Evidence of similar predatory behavior has been recorded in a specimen of *E. bairdi* collected in Brewster County, Texas (Olson 1967. Texas J. Sci. 19:99–106). Approximately 33 km SSW of Alpine, Texas, a male of the species, ca. 136 cm long, was observed resting inside two or three cliff swallow nests it had apparently broken open. While this Brewstser County snake was not observed hunting and preying on the swallows, its stomach contents were examined after it was collected and found to comprise five adult cliff swallows.

Returning to this Frio River location on the same date in 2001, I found no active nests and only two or three empty nests from the previous year. However, ca. 100 m downstream, swallows had established a new nesting site that contained many nests. This downstream location had been uninhabited the year prior during the time the above incident was witnessed.

The Real County snake described here was not collected, so measurement data are unavailable. However, based on measurements of the cliff obtained with an optical laser range calculator, the length of the snake was estimated at well over 132 cm.

While *E. bairdi* is said to be chiefly "day-active" (Werler and Dixon, *op. cit*), the incident cited above is unique in my experience for taking place during the middle of a bright, sunny day. Of the perhaps two-dozen *E. bairdi* I have observed in the last four years, all were active after dark, or just at dusk.

EPICRATES SUBFLAVUS **(Jamaican Boa). FORAGING BEHAVIOR.** The endemic Jamaican Boa (*Epicrates subflavus*), locally known as "Yellowsnakes," are known from three cave systems: Windsor (Trelawney), Green Grotto (St. Ann), and St. Clair (St. Catherine) (Prior and Gibson. 1997. Herpetol. Rev. 28:72–73). Bat predation has only been observed at Windsor Great Cave (Koenig and Schwartz 2003. Herpetol. Rev. 34:374–375; Vareschi and Janetzky 1998. Jamaica Nat. 5:34–35). Here we report field observations of *E. subflavus* roosting and foraging on bats in two additional cave systems in Jamaica.

We surveyed Ratbat Hole (Botany Bay, St. Thomas) on 16 December 2001 and 25 March 2002. This cave, known among local guano collectors, is about 4 km E of the satellite dish of Jamaican Communications on the main road from Kingston to Morant Bay, and can be reached after a 20-min steep hike north from Botany Bay. The main entrance is 5 m wide and about as tall, leading to a 15–20 m vertical passage. This cave is surrounded by karst, interspersed with low secondary dry scrub, and contains at least four bat species that have sharp seasonal variations in population density (Dávalos and Eriksson 2003. Caribb. J. Sci. 39:140–144). On our first visit we found an adult *E. subflavus* on the cave entrance, with a bat in its digestive tract. During our second visit we found a *E. subflavus* foraging for bats as they emerged and thereafter, from 1830 h to 2100 h. The boa made numerous unsuccessful attempts to capture bats identical to those described by Prior and Gibson (*op. cit.*).

We visited Monarva Cave (Revival, Westmoreland) on 5 December 2001 and 21 March 2002. Monarva is a locally well-known dry passage cave in the Negril Hills and is known to harbor populations of at least seven bat species (Dávalos and Erickson, *op. cit.*). Monarva is surrounded by the hamlet of Revival, pasture fields, and secondary vegetation. On our first visit we found an adult *E. subflavus* on the cave wall, 20 m along the steep passage that funnels thousands of bats from the inner chambers to the two-meter wide cave entrance. This animal remained in the same place throughout our visit, from 1900–1945 h. On our second visit, ca. 2000 h, we found a juvenile *E. subflavus* 3 m into the cave and moving out toward the vegetation at the entrance.

These observations confirm the presence of this threatened species (Hilton-Taylor 2000. IUCN Red List of Threatened Species. IUCN, Gland. xviii + 61 pp.) in the parishes of Westmoreland and St. Thomas, where previous reports claimed they were abundant but remained unvouchered (Gibson 1996. Dodo, J. Wildl. Preserv. Trusts 32:143–155). We also add two new localities to the handful of records of *E. subflavus* in Jamaican cave systems and confirm bat predation at Ratbat Hole. The dearth of observations on the ecology of this boine and the possible threat of human intervention in these cave systems warrant further research to determine the importance of the caves for both bats and snakes.

We thank the Department of Mammalogy at the American Museum of Natural History, the Center for Environmental Research and Conservation at Columbia University, and Elizabeth R. Dumont for providing financial support for our field trips.

EUNECTES MURINUS **(Green Anaconda). SUBDUING BEHAVIOR.** Constricting snakes coil around their prey preventing the prey from breathing. Additionally, they may cause circulatory arrest in their prey by applying pressure to the thoracic cavity that prevents the prey's heart from beating (Hardy 1994. Herpetol. Rev. 25:45–47). Here, I present evidence that when a constrictor handles potentially dangerous prey, the violence of the attack, and method of constricting might produce structural damage to the prey that reduces its ability to defend itself or escape. The following observations were taken in the Venezuelan llanos, Distrito Muñoz, Apure State (7°30'N, 69°18'W).

On 26 April 1992, a female anaconda (455 cm total length, 46 kg mass), during the process of killing a young capybara (2.5 kg mass) dislocated the capybara's spine at the cervical level. The snake did not eat her prey because apparently other capybaras attacked her. The capybara was found floating in the river the next

day and examination of the body showed that the capybara had a dislocated spine and evidence of anaconda teeth marks on its skin, matching the size of the snake's head.

On 24 March 1992, I found a female anaconda (413.5 cm TL; 40 kg mass) that regurgitated a female white-tailed deer (*Odocoileus virginianus*) weighing 10 kg. Upon examination of the regurgitated deer, I found that it had two broken ribs. I assume that the constriction process caused the deer's ribs to break.

On 27 January 2001, a female anaconda (460 cm TL) regurgitated a full-grown male white-tailed deer (*O. virginianus*) that had a disjointed spine at the cervical level.

In May 1999, a large anaconda (ca. 450 cm TL) was observed constricting a large (ca. 180 cm TL) spectacled caiman (*Caiman crocodilus*). During the process of constriction, it was apparent because of the angle between the caiman's tail and body, that the caiman's spine was broken (Fig.1).

In a recent account, an anaconda constricted a white collared peccary (*Tayassu tajacu*) (Valderrama and Thorbjarnarson 2001. Herpetol. Rev. 32:46–47) and the authors reported that: "At some point, a muffled crackling sound was heard, resembling that of many bones breaking all at once." It is uncertain if the bones (e.g., ribs) of the peccary were actually breaking or if the sound was that of vertebrae being dislocated. The following statement by the authors: " ...the snake coiled itself round the peccary's torso and squeezed, visibly stretching the peccary length-wise..." suggests the latter rather than the former.

The evidence presented here demonstrates that constriction by anacondas can produce structural damage to prey in the form of broken bones and dislocated vertebrae. Hardy (*op. cit.*) argues that the violence and pressure exerted on the prey is higher than what is needed to cause suffocation and contends that the violence and excessive pressure serves the purpose of producing circulatory arrest. While I do not disagree with Hardy's interpretation, I believe the extra pressure and violence of the strike might also serve the purpose of disjointing the spine or breaking ribs to reduce a prey's ability to escape or defend itself and to expedite death.

I thank the Wildlife Conservation Society, National Geographic Society, and Asociaccion para la Conservacion y Recate Ecologico ACRE, Zoo de Doue la Fontaine-France for financial and logistic support. I also thank COVEGAN, Estación Biologica Hato El Frío, for permits to work on their properties. I thank Tony Crocceta for providing photographic material. I am also in debt to M. Quero, P Azuaje, Mirna Quero, J. Thorbjarnason, M, Muñoz for their cooperation in the development of this research.

FIG. 1. Female Green Anaconda (ca. 450 cm TL) found constricting a large Spectacled Caiman (ca. 180 cm TL) in the Venezuelan Llanos. It is apparent that the spine of the caiman has been dislocated.

FORDONIA LEUCOBALIA (Yellow-Bellied Mangrove Snake) and ***MYRON RICHARDSONII*** (Richardson's Mangrove Snake). **DIURNAL FEEDING and PREY TYPE.** Snakes of the Homolopsinae, a lineage of aquatic colubrids, are found throughout southern Asia and northern Australia. Most species are piscivorous and ingest prey head first to assist digestion (Mori 1998. J. Herpetol. 32:40–50). All species in Australia are considered to be nocturnal (Gow 1989. Graeme Gow's Complete Guide to Australian Snakes. Angus and Robertson Publishers, North Ryde. 171 pp.). *Fordonia leucobalia* is reported to feed predominantly on Fiddler Crabs (*Uca* spp.), and occasionally on the Mud Lobster (*Thalassina anomala*) and shrimps (Shine 1991. Copeia 1991:120–131). Very little is documented regarding the feeding habits of *Myron richardsonii* apart from Shine (1991, *op. cit.*) who suggested it feeds on a variety of fish. We report herein several observations (MN) of these two species feeding by day in the mangroves of Ludmilla Creek, Darwin Harbour, Australia (12°25'S, 131°50'E) during 1998, with additional notes on prey consumed and methods of ingestion.

On 3 March, at ca. 1400 h, a snake (ca. 40 cm TL), identified as *F. leucobalia* according to Gow (1989, *op cit.*), was observed within the mangrove forest. The snake was wrapped around a large male Fiddler Crab (*Uca flammula*). The snake did not consume the crab and left it alive before moving down a nearby crab burrow, perhaps as a result of being disturbed by the observer.

On 3April, at ca. 1200 h, a *F. leucobalia* (brown dorsally and yellow ventrally) was observed on a creek bank ingesting a *T. anomala*. After ca. 10 min the snake ingested the lobster's tail, biting firmly down to displace the head, creating a clearly audible crunching sound. The snake consumed only the tail of the lobster, leaving the head in the mud.

On 13 April, at ca. 1500 h, a reddish-black *F. leucobalia* was observed within a channel ingesting a *T. anomala* as described above. On this occasion a second *F. leucobalia* (black and white morph) approached and began to coil around the first. The first snake then consumed the tail of the mud lobster as described above and moved away from the second snake rapidly.

On 2 March, at ca. 1500 h, a *M. richardsonii* was sighted on an exposed track. On close inspection, there appeared to be a black-colored nudibranch (Gastropoda) in the snake's mouth. The species could not be determined because it was almost completely encased in the snake's mouth.

The above observations report several previously undocumented phenomena. First, these observations document diurnal feeding in both *F. leucobalia* and *M. richardonii*. Both species had been regarded as strictly nocturnal (Gow 1989, *op. cit.*). Although observed active by day throughout the year (MN, pers. obs.), feeding activities were only observed from March to April, presumably when prey are most abundant (Davis 1985. *In* Bardsley et al.

[eds.], Coasts and Tidal Wetlands of the Australian Monsoon Region, pp. 297–312, NT branch of the Australian Marine Sciences Association, and the North Australia Research Unit of the Australian National University, Darwin; Nobbs 1999. Ph.D. Thesis, Northern Territory University, Darwin). Second, our observations suggest that *F. leucobalia* disengage the tails of their crustacean prey prior to ingestion. It has been reported that homolopsines ingest certain prey whole (e.g., fish, frogs), head or tail first, depending on initial bite position (Mori 1998, *op. cit.*), although Jayne et al. (2002. Nature 418:143) suggested that *F. leucobalia* remove and consume parts of their crab prey, such as the legs, if they are too large to consume whole. Third, these observations document *F. leucobalia* coiling around a crab. It seemed that this coiling behavior served as a prey holding technique, rather than an attempt at constriction to enable the snake to bite the enlarged claw of the male *U. flammula*, thereby subduing it prior to ingestion (D. Lawson, pers. comm.). This observation agrees with those of Shine and Schwaner (1985. Copeia 1985:1067–1071) and Jayne et al. (2002, *op. cit.*) who noted a similar coiling and prey consumption behavior in *F. leucobalia*. Finally, we document for the first time the consumption of a nudibranch by *M. richardsonii*. More observations would confirm whether or not this prey is uncommon for *M. richardsonii*. Homolopsine snakes of Darwin Harbour may partition prey among the three species, as described for Singapore homalopsines (Jayne et al., *op cit.*), with the Dog-faced Mangrove Snake (*Cerberus rhynchops*) consuming principally fish, *F. leucobalia* consuming principally crustaceans, and *M. richardsonii* consuming a combination of fish and gastropods.

We are grateful to Mick Guinea, Dennis Lawson, Keith McGuinnness, and Rick Shine for their feedback, advice, and assistance.

BLAMIRES***, Faculty of Science, Information Technology and Education, Northern Territory University, Darwin NT 0909, Australia (e-mail [MN]: madeleine_nobbs@hotmail.com). *Present address: Heydon-Laurence Building A08, School of Biological Sciences, University of Sydney, Sydney NSW 2006, Australia.

LACHESIS STENOPHRYS (Bushmaster). **REPRODUCTION.** The Bushmaster is unique among neotropical pit vipers in that it lays eggs rather than giving birth to live young. On 15 May 1995, a gravid female *Lachesis stenophrys* from Penshurt, Limon, Costa Rica, was received by Instituto Clodomiro Picado. The snake was individually housed in a cage, where it was offered water and mice. On 14 August 1995, the female laid 11 eggs averaging 40.29 ± 0.14 mm in diameter (range 40.1–40.5 mm), 64.15 ± 5.0 mm in length (range 60.3–70.9 mm) and 71.55 ± 1.47 g in weight (range 69.7–74.2 g). Hatching occurred in November and the duration of incubation averaged 106.63 ± 1.12 days (range 105–108 days). The 11 neonates were weighed and measured immediately and averaged 55.1 ± 2.3 g in weight (range 52.6–59.3 g) and 486.67 ± 5.7 mm in total length (range 480–490 mm). This clutch had a longer incubation time and greater mean total length and weight than a clutch reported by Ripa (1999. Bull. Chicago Herpetol. Soc. 34:45–92). Ripa (*op. cit.*) reported an incubation time of 75–77 days at 24°C, mean neonate total length of 406 mm, and weight of 45 g for a clutch of *L. stenophrys*.

We thank Rodrigo Aymerich and Gerardo Serrano for their cooperation, and Mahmood Sasa for his comments and review of this note.

LAMPROPELTIS GETULA (Common Kingsnake). **ENDOPARASITES.** Thirty-seven *Lampropeltis getula* (Colubridae) from the Natural History Museum of Los Angeles County, Los Angeles (LACM) were examined for endoparasites. A mid-ventral incision was made in the body wall and organ surfaces and mesenteries in the posterior portion of the body cavity were visually examined for helminths. One male (LACM 102538) from Riverside County, California, USA, collected 16 May 1958 contained 7 tetrathyridia (tapeworm larvae) of *Mesocestoides* sp. embedded in mesenteries. Prevalence of infection (infected snake/sample examined x 100) was 3%. The helminths were deposited in the United States National Parasite Collection, Beltsville, Maryland as USNPC 92016.

The occurrence of tetrathyridia of *Mesocestoides* sp. in snakes of the world has been summarized by McAllister et al. (1991. J. Parasitol. 77:329–331). Additional records of *Mesocestoides* sp. in the North American colubrids *Arizona elegans, Masticophis lateralis,* and *Rhinocheilus lecontei* are listed in Goldberg and Bursey (2001. Bull. So. California Acad. Sci. 100:109–116) and for the North American viperids *C. atrox, C. mitchellii, C. molossus, C. pricei, C. ruber, C. viridis,* and *C. willardi* are listed in Mankau and Widmer (1977. Jap. J. Parasitol. 26:256–259); Bolette (1997. J. Parasitol. 83:751–752); Goldberg and Bursey (1999. Herpetol. Rev. 30:44–45); Goldberg and Bursey (2000. Herpetol. Rev. 31:104). *Lampropeltis getula* represents a new host record for tetrathyridia of *Mesocestoides* sp.

We thank D. Kizirian (Natural History Museum of Los Angeles County) for permission to examine specimens.

BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

LAMPROPELTIS PYROMELANA (Sonoran Mountain Kingsnake). **ACTIVITY**. Most authors suggest that *Lampropeltis pyromelana* is primarily diurnal (Fowlie 1965. The Snakes of Arizona, Azul Quinta Press, Fallbrook, California). In his unpublished master's thesis, Woodin (1956. The Ecology and Geographic Variation of the Arizona Mountain Kingsnake *Lampropeltis pyromelana*. Univ. of California Berkeley) indicated activity between 0700 and 1800 h (N = 15 observations), and concluded "*L. pyromelana* is a distinctly diurnal species." Woodin (*op. cit.*) also noted "no specimens have been found active at night."

Following Woodin's publication, Bowker (1994. Herpetol. Rev. 25:124–125) reported on 11 individuals from Camp Geronimo

(Gila Co., Arizona), noting activity between 1140 and 1810 h, with a peak capture rate between 1500 and 1600 h.

In the Animas Mountains (Hidalgo Co., New Mexico), we logged 6651.3 h searching for snakes in April through November (1994–1999, 2002). We recorded 54 *L. pyromelana* captures (44 male, 10 female), for a mean search effort of 123.2 h per specimen. These data evidence activity between 0712 and 2015 h (all times 7 h offset GMT) at 1798–2326 m elevation. Generally, capture rates (Table 1) prior to 1500 h were substantially lower than the overall mean, whereas capture rates after 1500 h were higher. Additionally, capture rates tended to be lowest at mid-day hours (ca. 1100–1500 h), when temperatures are usually highest. Because daylight hours vary across seasons, capture times were compared to sunrise and sunset times to better assess diel activity. No captures were recorded within 1.0 h after sunrise, and only one capture was recorded within 2.0 h after sunrise (1.5 h after sunrise). However, we recorded seven captures within 1.0 h of sunset, and 10 captures within 2.0 h of sunset. One capture occurred 2.3 h after sunset. These data suggest that *L. pyromelana* in the Animas Mountains may be most active in the late afternoon, evening, and dusk hours. However, activity patterns inferred from these capture data may also reflect collecting bias: approximately 88% of the search hours fell between 0800 and 1800 h, and 89% of the search effort occurred from July through October.

Observations of *L. pyromelana* from Municipio Namiquipa (Chihuahua, Mexico) suggest that *L. pyromelana* may be nocturnal under certain conditions. On 09 August 2002, we found a *L. pyromelana* crawling on the surface at 2130 h, approximately 2.6 h after sunset, at an elevation of 2185 m and an ambient temperature of 18.3°C. This individual was an adult female (SVL 740 mm, TL 910 mm) that had recently ingested a *Sceloporus jarrovii* (SVL 68 mm). Together, predator and prey were 137 g. On 10 August 2002 we observed another *L. pyromelana* crawling on the surface at 0024 h, approximately 5.5 h after sunset, at an elevation of 1743 m and an ambient temperature of 16.6°C. This individual was an adult female (SVL 760 mm, TL 940 mm, mass 145 g). These Mexican specimens were deposited at the Herpetological Collection of Unidad de Biología, Tecnología y Prototipos (UBIPRO 10172, 10190). We also report activity for a tricolor *Lampropeltis* (unvouchered), identified as *L. pyromelana*, from Municipio Tlahualilo (Durango, Mexico). The specimen was observed active at 2134 h (2.8 h after sunset) on 9 June 2000 at 1099 m elevation. However, this record seems problematic because the topography and vegetation of this area do not resemble those typically associated with *L. pyromelana*.

TABLE 1. Diel distribution of search efforts and capture rates for *Lampropeltis pyromelana* in the Animas Mountains (Hidalgo Co., New Mexico). Data were collected from April through November (1994–1999, 2002); 89% of the search effort occurred from July through October.

Hour	Total Search Effort (h)	Captures	Per Capita Search Effort (h)
0700	237.0	1	237.0
0800	460.6	4	115.2
0900	639.8	5	128.0
1000	726.5	6	121.1
1100	688.5	2	344.3
1200	635.5	5	127.1
1300	565.0	0	>565.0
1400	526.5	2	263.3
1500	528.5	6	88.1
1600	483.5	12	40.3
1700	387.0	4	96.8
1800	257.8	2	128.9
1900	125.5	4	31.4
2000	22.5	1	22.5

Collectively, the observational data presented here support earlier conclusions of a generally diurnal activity pattern for *L. pyromelana*, but further suggest that *L. pyromelana* may be most active in the late afternoon and dusk hours at certain latitudes. We also document nocturnal activity in *L. pyromelana*.

Submitted by **MATTHEW J. INGRASCI**, Department of Biological Sciences, University of Notre Dame, Notre Dame, Indiana 46556-0369, USA (e-mail: mingrasc@nd.edu), **JULIO A. LIOPHIS POECILOGYRUS (NCN). **ENVENOMATION.** This species has been reported recently from Venezuela (Dixon and Markezich 1992. Texas J. Sci. 44:131–166; Fuentes and Barrio 1999. Herpetol. Rev. 30:54; Rivas et al. 2002. Herpetol. Rev. 33:68). All species of the genus *Liophis* are known as quiet and inoffensive snakes, but presenting rear fangs. Handling by me and collaborators never resulted in a bite before the incident reported herein. We believe that this is the first reported case of envenomation by this species in Venezuela.

On 11 July 1999, in the summer camp Wai Tuna (km 303 along the road El Dorado-Santa Elena de Uairén, Gran Sabana, Bolívar State) some tourists under my care cornered a 55 cm TL snake, and called me quickly. I captured the snake by hand, being familiar with this species. The instinctive reaction of the snake being handled was to bite at the conjunction of the two first phalanges of the fourth finger of my left hand. It had its jaws clamped around my finger for approximately 3 min. I did not free myself or shake it off because I preferred to wait in order to let the snake release its grip on its own. The finger showed two small wounds, but both corresponded to the same right fang. After washing the wound with soap, I applied a "Aspivenin" suction device, albeit probably too late to be effective, although some blood was removed. Immediately, the two phalanges became swollen, and exhibited a severe dark purple color in the bitten area. Several minutes later, the third phalange was swollen. The general sensation was not pain, but numbness. Only if the finger was touched did I feel some pain. Twenty minutes later the swelling expanded to the third finger. I experienced an increasing pulsation as well as a rather bothersome tingling sensation. 1.5 h later the swelling had extended to the dorsum and palm of the hand. Some swelling also took place on the third phalanges of the rest of the fingers, except for the thumb.

There, it stabilized and stopped.

I made the decision to consult a person with experience in snake bites in the Santa Elena de Uairén-El Paují- Ikabarú area (Luis Scott). He had never seen a similar case. He, along with the doctors of Hospital Rosario Vera Zurita at Santa Elena de Uairén decided to prescribe an intravenous steroid (hydrocortisone in lieu of an antihistamine), an analgesic (Ibuprofen), and an antibiotic to prevent infectious complications.

The medical report four hours post bite, with the patient in good general condition, was as follows: bite by a snake (*Liophis poecylogyrus*, Colubridae) at the junction of the first and second phalanges of the fourth finger on the left hand (signs of coloration, temperature, edema and local congestion) with pain when touched and/or moved.

15 h post bite, the situation was unchanged, with a slight extension of the edema.

19 h post bite (after a short sleep of 4 h) the dorsum and palm inflammation was considerably reduced. A slight discomfort was noted in the left axilla.

22 h post bite, the general situation continued to improve (the inflammation goes down) but there was still pain to touch and movement.

48 h post bite, the swollen fourth finger and hand in general remitted considerably, the edema having extended to the dorsal and ventral parts of the first phalange notwithstanding.

60 h post bite, the finger recovered some mobility and the inflammation went down further.

72 h post bite, the finger recovered its mobility to ca. 60% and the inflammation was reduced to a minimum. The edema, however, was still in the first phalanx, especially in the dorsal region around the nail.

96 h post bite, the finger recovered its mobility further with the edema still present. Ibuprofen administration is suspended.

120 h post bite, the finger regained almost complete mobility with the edema still present. The antibiotic administration is reduced to one dose per day.

After one week, the finger was fully mobile, although some pain was felt when touched for yet another week when the edema disappeared completely.

LYSTROPHIS DORBIGNYI (Nariguda) and ***HELICOPS INFRATAENIATUS*** (Cobra-D'Água). **PREDATION.** Despite the great variety of taxa known to prey on snakes, records of predation on Neotropical species remain scarce. Current information about predation on *Lystrophis dorbignyi* consists of only one record, reporting the presence of juvenile specimens found in the stomach of predatory birds, such as the Limpkin, *Aramus guarauna* (Aves: Aramidae) (Orejas-Miranda 1966. Copeia 1966:193–205). No data addressing predation on *Helicops infrataeniatus* exist. Here we describe several instances of predation on *L. dorbignyi* and *H. infrataeniatus* by a pair of Burrowing Owls, *Speotyto cunicularia* (Aves, Strigidae).

Observations were made in an area of sand dunes located in the Municipality of Balneário Pinhal (30°17'30"S, 50°15'55"W), on the coastal plain of Rio Grande do Sul, Brazil. At 0830 h on 12 December 2001, we found three individuals of *L. dorbignyi* associated with the burrow of a pair of *S. cunicularia*. One of the individuals (male, 235 mm SVL) was found dead inside the burrow whereas the others (female, 226 mm SVL; male, 238 mm SVL) were severely injured, but still alive, just outside the burrow entrance. At 1100 h, we re-inspected the burrow, and found yet another injured *L. dorbignyi* (female, 238 mm SVL) next to it. At 1000 h on the next day, we found yet another dead *L. dorbignyi* (male, 230 mm SVL), and nine days later, a small part of the body of a sixth individual was found.

At 1000 h on 3 January 2002, when we were approaching the same burrow, one of the birds released the posterior portion of a female *H. infrataeniatus*. The tail length allowed us to estimate its size as ca. 325 mm SVL. The other bird was on a nearby dune and also abandoned the posterior portion of a female *H. infrataeniatus*, whose size was estimated at 245 mm SVL.

The time when we found the recently captured (still alive) individuals of *L. dorbignyi* coincides with that of the activity of this exclusively diurnal species (Oliveira 2001. Dissertação de Mestrado, Depto. de Zoologia da Universidade Federal do Rio Grande do Sul. 96 pp.) and led us to believe that the snakes were captured while active on the ground. As *H. infrataeniatus* has nocturnal and diurnal activity, as do Burrowing Owls (Sick 1977. Ornitologia Brasileira. Editora Nova Fronteira, Rio de Janeiro. 912 pp.), the finding of dead specimens doesn't allow us to infer the period in which they were captured. *Helicops infrataeniatus* is a highly aquatic species, but occasionally individuals are found on the ground. In January, when the observations were made, all local ponds were dry, suggesting that the snakes were captured out of water.

The length of the five measured specimens of *L. dorbignyi* is similar to that of the smallest specimens recorded in December in the sand dunes of Balneário Pinhal (Oliveira 2001, *op. cit.*). Individuals measuring less than 250 mm correspond to 14.5% of all individuals collected in that month (N = 69). Thus, it is possible that *S. cunicularia* selects this kind of prey by its size, targeting small individuals.

Four specimens of *L. dorbignyi* and two *H. infrataeniatus* are deposited in the collection of the Museu de Ciências e Tecnologia da Pontifícia Universidade Católica do Rio Grande do Sul (MCP 12668–71, 12734–35). We thank Douglas A. Rossman (Luther College, Iowa) for suggestions on this manuscript, and Carla Suertegaray Fontana (PUCRS) for information on the owls. One of us (RBO) benefited from a graduate fellowship from Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES).

NATRIX MAURA (Viperine Snake). **MARINE INHABITATION.** Natricine snakes generally occupy habitats near freshwater. One of the few exceptions is the North American species *Nerodia fasciata*, which includes populations adapted to brackish waters of estuaries and seacoasts (Zug et al. 2001. Herpetology. Academic Press, 630 pp.). In southern Europe and northwestern Africa, *Natrix maura* is commonly found in habitats near riverbanks, lagoons, and freshwater ponds; it feeds mostly on fish and amphibian larvae (Braña 1998. *In* Salvador and Ramos [eds.], Fauna Ibérica, Vol. 10: Reptiles, pp. 440–454. Museo Nacional de Ciencias Naturales, CSIC). Also, it has been reported to occasionally occupy pools of seawater in intertidal coastal zones (Cabot and Olea 1978. Doñana, Acta Vertebrata 5:107; Galán 1987. Mustela 3:64–69; Pino et al. 1998. *In* Santos et al. [eds.], Inventario de las Areas Importantes para los Anfibios y Reptiles en España, pp. 161–163, Ministerio de Medio Ambiente). In 2000 and 2001 several specimens of *N. maura* were found near the sea on islands and islets off the Galician Coast (NW Spain). These snakes belonged to populations that would appear to depend solely on prey from the marine habitat. In July 2001 two large adult females (one animal: SVL 857 mm, TL 164 mm) were discovered at the foot of a cliff on the islet of Onza (UTM 29T NG08). This islet, with an area of 32 ha and located 6 km from the nearest coast, has no permanent fresh water. These aquatic snakes thus depend solely on food derived from marine waters. In August 2001, on the nearby island of Ons (UTM 29T NG09), with an area of 414 ha and located 3 km from the nearest mainland, four specimens of *N. maura* were sighted on the coast among the large boulders at the foot of the cliffs, in the rocky intertidal zone, and on the beach close to the sea. One of the snakes, which measured 445 mm TL, disgorged a marine fish, *Blenius pholis*, 83 mm TL.

On the Island of San Martiño (archipelago of the Cíes Islands, UTM 29T NG07), with an area of 146 ha and 3 km from the mainland, in August 1986, an individual of *N. maura* was found swimming in the sea 2 m from the shoreline. On this same island, in June 2000, an individual of *N. maura* was observed among the boulders on the seashore.

Additional research is needed to determine if occupation of marine environments has been accompanied by physiological adaptations in *N. maura*.

OXYRHOPUS RHOMBIFER RHOMBIFER (NCN). **DIET.** *Oxyrhopus r. rhombifer* is a terrestrial, mainly nocturnal, pseudoboine snake from southeastern and southern Brazil to northeastern Argentina and Uruguay (Bailey 1970. U.S. Nat. Mus. Bull. 297:229–235). Known prey items are small or ophiophorm lizards (Cei 1993. Reptiles del Noroeste, Nordeste y Este de la Argentina. 950 pp. Museo Regionale di Scienze Naturali, Torino; Yanosky et al. 1996. Herpetol. Nat. Hist. 4:97–109; Maschio et al. 2003. Herpetol. Rev. 34:71), rodents (Lema et al. 1983. Comun. Mus. Ci. PUCRS 26:41–121), and anurans (Yanosky et al., *op. cit.*). With regard to lizards, recorded prey include representatives of the families Anguidae (Maschio et al., *op. cit.*) and Gymnophthalmidae (Cei 1993, *op. cit.*).

We dissected one adult male of *O. r. rhombifer* (Museu de Ciências e Tecnologia da Pontifícia Universidade Católica do Rio Grande do Sul, MCP 2698; SVL 458 mm, mass 31.9 g) from the municipality of Porto Alegre (30°01'S, 51°13'W), southern Brazil; its stomach contained a nearly complete tail of a Tropical House Gecko (*Hemidactylus mabouia*) (MCP 1244 - prey items collection). This is the first record of *H. mabouia*, and the family Gekkonidae, as prey of *O. r. rhombifer*, although this species of lizard was previously cited as prey for *O. guibei* (Andrade and Silvano 1996. Revta. Bras. Zool. 13:143–150). These data provide further evidence that pseudoboine snakes feed primarily on small lizards and mammals (Duellman 1978. Misc. Publ., Univ. Kansas Mus. Nat. Hist. 65:1–352; Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150).

We thank Robert A. Thomas (Loyola University New Orleans) and John Measey (Laboratoire d'Écologie des Sols Tropicaux, IRD / Université Paris) for making useful comments on earlier versions of this manuscript. One of us (GFM) benefited from a graduate fellowship from Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq).

PYTHON RETICULATUS (Reticulated Python). **SITE SELECTION, SLEEPING, and ESCAPE BEHAVIOR**. *Python reticulatus* is frequently encountered in many natural and man-made habitats, from sea-level to 1500 m, in Southeast Asia (Cox et al. 1998. A Photographic Guide to Snakes and Other Reptiles of Thailand and South-East Asia. Asia Books, Bangkok. 144 pp.). Although large and heavy adults are primarily terrestrial (Cox, *op. cit.*), juvenile *P. reticulatus* are highly arboreal. Numerous authors also report that this species is often found near water (Boulenger 1912. A Vertebrate Fauna of the Malay Peninsula from the Isthmus of Kra to Singapore. Reptilia and Batrachia. Taylor and Francis, London xiii + 294 pp.; de Rooji 1917. The Reptiles of the Indo-Australian Archipelago II Ophidia. E. J. Brill, Leiden xiv+ 334 pp.; Tweedie 1957. The Snakes of Malaya. Govt. Printing Office, Singapore. 143 pp.). Although an apparently well studied species, most references concern the prodigious size and dietary capabilities, together with reproductive and distributional data. Little is written about their activities, habits, and behavior in the wild. For example, *P. reticulatus* is often encountered coiled and resting ("sleeping") during daylight hours.

Herein we report on the behavior of 13 *P. reticulatus*. Two of us (MOS and YT) obtained data for eight 1.0–2.0 m TL individuals along Lo Po Creek, Tarutao Island, Satun Province, southwestern Thailand, and three of us (MOS, YT, and AJL) obtained data on

four 1.0–2.0 m TL individuals and a single 3.0 m TL specimen along the Phetchaburi River, Kaeng Krachen National Park, Phetchaburi Province, western Thailand. All observations were made during daylight hours. The 3.0 m TL individual was found under a fallen tree on a bend in the Phetchaburi River, and was in pre-ecdysis. But all of the smaller individuals were found sleeping, curled on branches overhanging a tidal, mangrove-fringed Lo Po Creek (Tarutao Island) or in the Phetchaburi River (KKNP). The sleeping pythons were at heights ranging from 2 to 15 m above the water, most being at the greater heights.

Both the Phetchaburi River and Lo Po Creek contained stretches of shallow water and sporadic deeper pools, particularly on the outer curve of bends. Lo Po Creek was also subject to a regular cycle of widely varying water depths because of its tidal nature.

All of the pythons were found over deeper water; none was observed sleeping over shallow stretches on either watercourse. Campden-Main (1970. A Field Guide to the Snakes of South Vietnam. Smithsonian Inst. Press, Washington. vi +114 pp.) indicated that he found pythons at Bien Hoa "under bridges over rapidly flowing streams" but he did not record the depth of the water at these locations. All pythons we disturbed (10 of 12) immediately uncoiled and dove from their branch, plunging into the water where they were easily caught. No python attempted to escape by moving along the branch or bridging to another branch. This escape behavior ("diving") would suggest why perches over relatively deep water were selected rather than those above shallow stretches. Large lizards (*Iguana*, *Varanus*) also escape in this manner but the eyes of most snakes, including those of pythons, lack foveae, and therefore high visual acuity (Tansley 1965. Vision in Vertebrates. Chapman & Hall, London. vii + 132 pp.). Young pythons appear to be deliberately selecting suitable perches over sufficiently deep water for safe escape, but their means of determining suitability of perches remains a mystery.

We thank YAP Films and Animal Planet for funding and support of the project.

REGINA SEPTEMVITTATA (Queen Snake). **DIET.** Adult *Regina septemvittata* are thought to feed almost entirely on recently molted crayfish (Branson and Baker 1974. Tulane Stud. Zool. Bot. 18:153–171; Burghart 1968. Copeia 1968:732–737; Conant 1951. The Reptiles of Ohio. University of Notre Dame Press. 284 pp.; Minton 1972. Amphibians and Reptiles of Indiana. Indiana Acad. Sci. 346 pp; Penn 1950. Amer. Midl. Nat. 44:643–658; Wood 1949. Amer. Midl. Nat. 42:774–750). Adler and Tilley (1960. J. Ohio Herpetol. Soc. 2:28–29) reported a mudminnow and snail in the stomach of a *R. septemvittata*. Minton (*op. cit.*) also reported a catfish (as did Wood, *op. cit.*) and a dragonfly larva in the stomachs of *R. septemvittata*. Branson and Baker (*op. cit.*) reported the fantail darter, *Etheostoma flabellare*, to comprise 1.4% (N = 2) of the total stomach contents from their study. We are unaware of any published records for neonates.

On 9 May 2001, while performing a mark-recapture study of a snake community in Sandusky Bay, Ohio, USA (41°29'N, 82°49'W) the stomach contents of three neonate *R. septemvittata* were noted. All neonates appeared to be born the season before, making them ca. 8 months old. One female (15 cm TL, 4 g), regurgitated a 37.75 mm long by 7.30 mm wide crayfish cheliped. A second female (13.9 cm TL, 4 g), regurgitated a 21.75 mm long by 4.85 mm wide crayfish chela. A male neonate (16 cm TL, 4 g), regurgitated a zebra mussel, *Dreissena polymorpha* (shell, 8.55 mm L x 6.7 mm W), a dominant introduced member of the bivalve fauna, and an additional very digested crayfish chela. Wood (*op. cit.*) witnessed *R. septemvittata* feeding on dead crayfish. Our observations may substantiate that neonates feed on some crayfish carrion. Branson and Baker (*op. cit.*) had several neonates killed and consumed by crayfish in the laboratory. It is doubtful a neonate could feed on a portion of an active adult hard-shelled crayfish. It is unknown whether the neonates removed the appendage from a freshly molted crayfish or scavenged them. As these were the only stomach contents collected from neonates, crayfish chelae and chelipeds may make up an appreciable proportion of the neonatal diet. It is difficult to believe the bivalve was an incidental ingestion, as it was several times the size of the neonate's head and appeared broken at the site of attachment.

Submitted by **KENT BEKKER**, Graduate Studies at Bowling Green State University, Department of Biology, 217 Life Science Building, Bowling Green, Ohio 43402, USA, and Department of Herpetology, Toledo Zoological Society, and **JOE TIMAR**, Department of Herpetology, Toledo Zoological Society, P.O. Box 140130, Toledo, Ohio 43614, USA.

SISTRURUS CATENATUS (Massasauga). **AGGRESSIVE BEHAVIOR**. *Sistrurus catenatus* has been described as a sluggish and mild-mannered species (Klauber 1972. Rattlesnakes: Their Habitat, Life Histories, and Influence on Mankind. Univ. of California Press, Berkeley. 1533 pp.), and one of us (RAS) has even stepped on an individual without it even rattling. Others suggest that *S. catenatus* is rather irritable (Ernst 1992. Venomous Reptiles of North America. Smithsonian Institution Press, Washington, D.C. 236 pp.). The temperament of a particular species can vary from individual to individual, and both endogenous and exogenous factors have been reported to influence snake behavior (e.g., sex, body condition, reproductive status, and the thermal environment [Stevenson et al. 1985. Am. Nat. 1985:362–386; Reinert 1988. Copeia 1998:964–978]). Herein, we report on an unusually aggressive male *S. catenatus* (65.8 cm TL, 58.3 cm SVL, 210 g).

On 18 December 2002 while relocating snakes implanted with Holohil SI-2T transmitters at the Squaw Creek National Wildlife Refuge in NW Missouri, one of us (JRL) noted snake 046 to be surface active at 1319 h. The snake appeared to be basking from within a clump of dead reed canary grass (*Phalaris arundinacea*), with only a loop of its body exposed to direct sunlight. As I approached to ca. 3 m the clump of grass began to shake and a faint buzz from the rattle was heard. When I approached to within 1.5 m the snake emerged from its basking location, slowly approached

to within 0.15 m while I remained motionless and proceeded to strike at my boot two times before it withdrew and returned to its basking location. The entire incident took place over a period of not longer then five minutes. The snake's internal body temperature of 11.5°C was considerably higher then either the ambient air temperature 1 m above the soil surface (5.6°C) or the soil temperature 10 cm below the soil surface (4.7°C). When this same individual's pre-hibernation measurements were taken on 20 November 2002, it appeared to be in good condition and no external signs of infection were observed. The fact that the snake was surface active was not surprising considering the five days of warm weather prior to the observation; average high for 14–18 December 2002 1 m above the soil surface = 16.85°C. Out of hundreds of encounters with *S. catenatus* at this site, this is the first individual that has appeared to go out of its way to strike at a human. Whether this unusual behavior was an artifact of transmitter implantation (on 14 August 2002), a predatory defense, or a result of some environmental or physiological factor is unknown.

Submitted by **JAMES R. LEE,** and **RICHARD A. SEIGEL**, Department of Biological Sciences, Towson University, Towson, Maryland 21252, USA, and **FRANCIS E. DURBIAN**, Squaw Creek National Wildlife Refuge, P.O. Box 158, Mound City, Missouri 64470, USA (e-mail [JRL]: jlee21@towson.edu).

TANTILLA WILCOXI (Chihuahuan Black-headed Snake). **REPRODUCTION.** Information on reproduction in *T. wilcoxi* is that 1–3 eggs are laid in spring and summer (Behler and King 1979. The Audubon Society Field Guide to North American Reptiles and Amphibians. Alfred A. Knopf, New York. 743 pp.). The purpose of this note is to present additional data on one clutch and the first information on the testicular cycle. Two females, mean snout–vent length, SVL = 267 mm ± 45 SD, and eight males, SVL = 213 mm ± 34 SD, range = 168–261 mm were examined from the herpetology collection of the University of Arizona, Tucson. The left gonad was removed, dehydrated in ethanol, cleared in toluene, and embedded in paraffin. Histological sections were cut at 5 µm and stained with Harris' hematoxylin followed by eosin counterstain.

One female, UAZ 40402, SVL = 298 mm, collected 22 September from Santa Cruz County, Arizona, USA contained one oviductal egg that measured 27 x 8 mm (no histology was performed). Another female, UAZ 46148, SVL = 235 mm, collected 22 August from Sonora, México was not undergoing yolk deposition.

All males examined were undergoing spermiogenesis (sperm formation). This included two July males UAZ 26450, SVL = 261 mm from Cochise County, Arizona, USA, and UAZ 42234, SVL = 217 mm from Nuevo León, México, four August males: UAZ 28201, SVL = 230 mm, from Sonora, UAZ 39600, SVL = 168 mm (minimum size for spermiogenesis) from Cochise County, UAZ 42687, SVL = 208 mm from Durango, México, UAZ 48780, SVL = 251 mm from Cochise County, UAZ 50383, SVL = 195 mm from Cochise County, and one September male: UAZ 46338, SVL = 170 mm from Nuevo León.

Histological examinations of testes from *T. wilcoxi* males collected in spring will be needed before the monthly duration of spermiogenesis can be known.

I thank George Bradley (University of Arizona) for permission to examine specimens.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

THAMNOPHIS BRACHYSTOMA (Short-Headed Gartersnake). **MAXIMUM SIZE.** On 13 June 2002 I found a female *Thamnophis brachystoma* that was 458 mm SVL and 578 mm TL under trash next to the Penn Central railroad tracks, immediately northwest of the intersection of East 26th and Elm Streets in Erie, Pennsylvania, USA. This exceeds the maximum total length record of 559 mm (Conant and Collins 1998, Peterson Field Guide to Reptiles and Amphibians of Eastern and Central North America, 3rd ed. Expanded. Houghton Mifflin, Boston, Massachusetts, xviii + 616 pp.). Verified by Peter V. Lindeman. This urban population of *T. brachystoma* is outside of its natural range (Hulse et al. 2000, Amphibians and Reptiles of Pennsylvania and the Northeast, Cornell University Press, Ithaca, 419 pp.). Color slides of the specimen were deposited in the Carnegie Museum of Natural History (36995-1–2). This individual is currently being maintained in captivity, and will be deposited in the Carnegie Museum upon its death.

Submitted by **MARK LETHABY**, 535 East 29th Street, Erie, Pennsylvania 16504, USA.

THAMNOPHIS CYRTOPSIS (Black-necked Garter Snake). **ATTEMPTED PREDATION**. At 1735 h on 5 July 2000, at Cottonwood Creek (Yavapai Co., Arizona, USA), a permanent, intermittent Sonoran Desert stream, I observed an adult *Lethocerus medius* (giant water bug, total length 61 mm) attempt to prey on a neonate *Thamnophis cyrtopsis* (SVL 300 mm, tail length 70 mm). The *L. medius* was perched on a rocky ledge submerged ca. 20 cm in a shallow pool, and had grasped the snake mid-body. I observed the two for several minutes. The snake coiled around the insect tightly, and therefore I was unable to determine if the insect's proboscis was embedded into the snake. After I captured both individuals, the *L. medius* released the snake. Several scales were damaged, exposing the dermis on the ventral side of the snake near the region where the *L. medius* had grasped it. The snake was marked by scale clipping, and released as part of a long-term population study. The *L. medius* is preserved at Grand Canyon University.

I thank Robert L. Smith, Department of Entomology, University of Arizona for *Lethocerus* species identification. I also thank Thomas R. Jones and Frank R. Hensley for review of a previous draft of this note.

Submitted by **ANGELA L. SCHWENDIMAN**, Department of Biology, Grand Canyon University, 3300 West Camelback Road, Phoenix, Arizona 85017, USA; e-mail: aschwendiman@earthlink.net.

THAMNOPHIS GODMANI (Godman's Garter Snake). **DIET**. Members of the genus *Thamnophis* consume a wide variety of vertebrates and invertebrates, including small mammals, amphib-

ians, fish, lizards, slugs, earthworms, and leeches (Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. Univ. Oklahoma Press, Norman, Oklahoma. 332 pp.). Venegas-Barrera and Manjarrez (2001. Herpetol. Rev. 32:187) provided the first published record of ophiophagy in *Thamnophis*. Few data exist on the natural history and diet of *T. godmani*. Rossman et. al. (*op. cit.*) reported that after collection an individual regurgitated a mouse.

On 12 July 2002 we collected a male *T. godmani* (TL 562 mm , 36 g) 3 km E of Omilteme, Guerrero, Mexico (~ 2000 m elev.). It was found at the edge of a cleared field in a rock pile, near the base of a heavily forested mountain slope. This individual had a noticeable mid-body bulge, and after palpation regurgitated a large *Rhadinaea taeniata aemula* (TL 465 mm, 13 g). This represents the second recorded prey item for *T. godmani*, and the second record of ophiophagy in *Thamnophis*.

We thank James R. Dixon and Jonathan A. Campbell for their help with the identification of the snakes. Emerenciano R. Rivera provided valuable assistance in the field. James M. Mueller and Jonathan A. Campbell kindly reviewed the manuscript and provided additional comments.

BRYSON, JR.***, Department of Biology, Sul Ross State University, Alpine, Texas 79832, USA, and **DAVID LAZCANO**, Laboratorio de Herpetología, Universidad Autónoma de Nuevo León, Apartado Postal - 513, San Nicolas de los Garza, Nuevo León, C.P. 66450, México. *Present address: Department of Herpetology, San Antonio Zoo, 3903 North St. Mary's Street, San Antonio, Texas 78212, USA (e-mail: rob_bryson2002@yahoo.com).

THAMNOPHIS SIRTALIS CONCINNUS (Red-spotted Garter Snake). **PREDATION**. Many anecdotes detail failed predation by snakes because prey were too large and/or awkward (e.g., Barton 1949. Copeia 1949:147; Sazima and Martins 1990. Mem. Inst. Butantan 52:73–79; Tamarck and Doherty 1993. Herpetol. Rev. 24:62). More rare are field observations in which prey approach the size limit of a predator. Such data are important in understanding foraging behavior and providing empirical links to experimental studies that address foraging theory (Arnold 1993. *In* Seigel and Collins [eds.], Snakes: Ecology and Behavior, pp. 87–115. McGraw Hill, Inc., New York). Herein we detail one such report for *Thamnophis sirtalis concinnus*.

Two of us (BKM, MAH) made these observations in the Halfway Creek drainage, Stillman Basin, Willapa Hills (southwestern Washington State, USA; 46°30'42"N, 123°08'53"W), a low-elevation (122 m) site on a Weyerhaeuser-managed Douglas-Fir (*Pseudotsuga menziesii*) tree farm. Observations were made along the riparian margin of a small (< 1 m wide), second-order tributary of Halfway Creek with a scattered Red Alder (*Alnus rubra*) overstory and a dense Sword Fern (*Polystichum munitum*) understory.

On 30 August 2002, at 1400 h, while collecting physical data during a stream survey of this tributary, we found an adult (SVL 65 cm) *T. s. concinnus* (lying near the base of a sword fern next to water) that had captured an adult Northern Red-legged Frog (*Rana aurora*) (SVL 80 mm). Based on size alone (Storm 1960. Copeia 1960:251–259; Licht 1986. Can. Field-Nat. 100:22–31), the frog was likely a female. When first encountered, the snake had a firm grasp on the shoulder of the frog, which was belly-up with its right foreleg inside the snake. We noted that the frog was engaged in serial inflation of its throat, which appeared to be a defensive response rather than typical breathing movements. During this initial observation period, other than throat inflation, the frog showed no signs of struggling, implying that it had tired from the initial encounter as it appeared otherwise healthy and robust. Further, the snake made little noticeable gain in its attempt to swallow the frog during the 15-min observation interval. As the snake was not advancing significantly, we left.

Upon completion of fieldwork at 1530 h, BKM returned to the location. The snake, still with the frog, had moved ca. 0.5 m to a more concealed location near an overhanging log and had made substantial progress in swallowing the frog. About two-thirds of the frog was now inside the snake. The frog was still positioned mostly belly-up but the hind legs stuck straight out together. The snake was compressing the frog to such an extent that the still exposed lower abdomen was now at least 20% larger than the original maximum girth of the frog. As BKM stepped down the bank to obtain a better view, he saw that the skin and underlying tissue on the frog's back was so stretched that it had ruptured, resulting in protrusion of viscera in a small pile extending ca. 4 cm. Following 10 min of observation, BKM measured the snake, which thrashed somewhat during measurement but made no effort to regurgitate the frog. During this second observation period, the snake had progressed a few millimeters further in swallowing the frog. Observations were terminated before the snake completely consumed the frog.

Extreme compression needed to swallow the frog suggests that, for its size, the *T. s. concinnus* was near its limit for the prey shape involved. The nature of the observation prevented us from precisely determining frog length, but a mass-SVL regression of *R. a. aurora* from Washington (MPH, unpubl. data) suggests that the female could be expected to have a mass of at least 40 g. Long time intervals characterize handling of awkward prey near the limiting size (e.g., Kupferberg 1994. Herpetol. Rev. 25:95–97). The 1.5-h interval over which observations were made underestimates handling and ingestion time, but total time might not be much longer as the snake had completed the difficult swallowing phase and the unobserved early portion of the bout was likely not lengthy as the frog would be expected to tire quickly (Pough et al. 1992. *In* Feder and Burggren [eds.], Environmental Physiology of Amphibians, pp. 395–436. The University of Chicago Press, Chicago). Time spent in predatory activities might be costly if those activities make a predator vulnerable (Arnold, *op. cit.*) as this *T. s. concinnus* seemed to be while ingesting the frog.

Weyerhaeuser (through Douglas E. Runde, Research Wildlife Biologist) facilitated studies on their lands. Forest and Fish Adaptive Management funding supporting the Science Division of the Habitat Program of the Washington Department of Fish and Wildlife (WDFW) that addresses headwater stream research made this contribution possible; WDFW personnel handling amphibians are permitted for this work.

USA (e-mail [MAH]: huntemah@dfw.wa.gov, [MPH]: hayesmph@dfw.wa.gov).

THAMNOPHIS SIRTALIS PARIETALIS (Red-sided Garter Snake). **ENDOPARASITES**. In the only study of the coccidia of *Thamnophis sirtalis parietalis*, Wacha and Christiansen (1974. J. Protozool. 21:483–489) described two species of *Eimeria* (Apicomplexa: Eimeriidae) from individuals collected in Iowa, USA. Herein we report on one of these species (*E. iowaensis*) from *T. s. parietalis* collected in southeastern Nebraska, USA.

During June–September 2001, six road-killed and five live *T. s. parietalis* were collected in Richardson and Nemaha counties, Nebraska. SVL was measured when possible (mean: 460 mm; range: 280–655 mm; N = 9) and fecal or intestinal samples from each snake were placed in 2.5% aqueous potassium dichromate ($K_2Cr_2O_7$) solution and kept at 20–23°C) for four weeks to allow coccidian oocysts to sporulate. Samples were screened for coccidia by centrifugal flotation in modified Sheather's solution (Duszynski and Wilber 1997. J. Parasitol. 83:333–336) that had been diluted with 2 parts water to retard wrinkling of the oocyst wall. Sporulated oocysts were measured under 1000x magnification and identified using characteristics in Wacha and Christiansen (*op. cit.*).

Two of the 11 samples (18%) contained oocysts of *E. iowaensis*; both hosts were from Richardson County. Oocyst measurements (N = 32) and structural features were consistent with those previously reported for *E. iowaensis* by Wacha and Christiansen (*op. cit.*). This is the first report of *E. iowaensis* from *T. s. parietalis* in Nebraska. *Eimeria iowaensis* has been previously reported from one of 25 *T. s. parietalis* in Iowa (Wacha and Christiansen, *op. cit.*), and from one (of one tested) *T. elegans vagrans* in New Mexico, USA, and one of 13 *Nerodia fasciata confluens* in Arkansas, USA (McAllister et al. 1995. J. Parasitol. 81:63–68).

Submitted by **JOHN A. HNIDA**, Department of Natural Sciences, Peru State College, Peru, Nebraska 68421, USA (e-mail: jhnida@oakmail.peru.edu), and **REBECCA J. CARPENTER**, 6234 Robin Lane #71, Manhattan, Kansas 66502, USA (e-mail: rcarpent@vet.k-state.edu).

THAMNOPHIS VALIDUS (Mexican Pacific Lowlands Gartersnake). **ENDOPARASITES.** Herein we provide the first report of endoparasites from *Thamnophis validus* which ranges in Baja California del Sur and portions of coastal Sonora, Sinaloa, Nayarit, Jalisco, Michoacán, and Guerrero, Mexico (Rossman et al. 1996. The Garter Snakes: Evolution and Ecology, Univ. Oklahoma Press, Norman. 332 pp.).

Thirty-two *T. validus* (mean SVL: 525 ± 112 mm SD; range: 323–745) from the Mexican states of Sonora, Sinaloa, and Nayarit were examined from the herpetology collections of the Natural History Museum of Los Angeles County, California (LACM) and the University of Arizona, Tucson (UAZ). Snakes were collected from 1960–1977. A mid-ventral incision was made in the posterior third of the body wall, and the coelomic cavity and visceral organs were visually examined for parasites. One of the snakes (LACM 7121) from Sonora harbored five larval nematodes in cysts in the mesentery, and a second specimen (LACM 58963) from Sinaloa harbored 41 metacercariae (larval trematodes) and one larval nematode in the mesentery. Nematodes were separated from the surrounding connective tissues, placed on a microscope slide, cleared in a drop of concentrated glycerol, and identified as larval *Porrocaecum* sp. Prevalence of infection (number of infected snakes/number of snakes examined x 100) was 2/32 (6%); mean (± 1 SD) intensity of infection (number of nematodes/number of infected snakes) was 3.0 ± 2.8 SD. They were placed in a vial of 70% ethanol and deposited in the United States National Parasite Collection, Beltsville, Maryland (USNPC) as 92783. Metacercariae were separated from the surrounding tissue, regressively stained in Delafield's hematoxylin, dehydrated in an ethanol series, cleared in xylene, mounted in balsam and identified as members of the superfamily Strigeoidea. The slide was deposited in the USNPC as 92782.

Adults of *Porrocaecum* sp. typically are found in the intestines of birds; eggs are ingested by earthworms, hatch and develop to third stage larvae (Anderson 2000. Nematode Parasites of Invertebrates: Their Development and Transmission, 2nd ed., CABI Publishing, Oxon, United Kingdom. 650 pp.). Animals that consume earthworms serve as paratenic (transport) hosts which transfer the nematode to the definitive avian host (Anderson, *op. cit*). In Mexico, in the state of Veracruz, the frogs *Eleutherodactylus rhodopsis* and *Leptodactylus melanonotus* have been reported to harbor larvae of *Porrocaecum* (Goldberg et al. 2002. Southwest. Nat. 47:293–299). Although *T. validus* is known to eat frogs and toads, and perhaps earthworms (Conant 1969. Bull. Amer. Mus. Nat. Hist. 142:1–140), the small number of larvae found in this study and the fact that two cysts were beginning to calcify suggest that *T. validus* was most likely an accidental host. *Thamnophis validus* represents a new host record for *Porrocaecum* sp. Sinaloa and Sonora, México are new locality records.

Adults of the Strigeoidea are parasites of birds and mammals; fishes and tadpoles often serve as intermediate hosts (Schell 1970. How to Know the Trematodes. Wm C. Brown Publishers, Dubuque, Iowa, 355 pp.). In Mexico, *Thamnophis eques* from the state of Mexico, and *Thamnophis melanogaster* from the state of Michoacán, have been reported to harbor metacercariae of *Diplostomum* sp., a strigeoid trematode (Pérez-Ponce de León et al. 2001. Comp. Parasitol. 68:9–20). *Thamnophis validus* is most likely an accidental host (calcified cysts were present), but does represent a new host record for strigeoid metacercariae. Sinaloa, Mexico is a new locality record.

We thank D. Kizirian (LACM) and G. Bradley (UAZ) for permission to examine *T. validus*.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu), and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA.

VIRGINIA STRIATULA (Rough Earth Snake). **PREDATION**. There are few published accounts of predation on *V. striatula*. Palmer and Braswell (1995. Reptiles of North Carolina, UNC Press, Chapel Hill, North Carolina. 412 pp.) report three colubrid snakes (*Coluber constrictor*, *Lampropeltis calligaster*, and *L. triangulum elapsoides*) to be predators. The Nine-banded Armadillo (*Dasy-*

pus novemcinctus) is known to consume *V. stiatula* (Breece and Dusi 1995. *In* Montgomery [ed.], The Evolution and Ecology of Armadillos, Sloths, and Vermilinguas. Smithsonian Inst. Press, Washington. 451 pp.). The only record concerning avian predation on *V. striatula* that I am aware of involves the Eastern Screech Owl (*Otus asio*; Gehlbach and Baldridge 1987. Oecologia 71:560–563).

On 2 December 2002 at 1130 h, air temperature 13°C, I observed a Northern Mockingbird (*Mimus polyglottos*) holding a *V. striatula* in its beak. The event took place in the yard of a rural farmhouse 4.6 km (air) N of Waverly, in Chambers Co., Alabama, USA. The bird was grasping the snake by the tail, immediately posterior to the vent. Upon my approach, the bird flew from the stone terrace where it was perched and sought refuge behind dense shrubbery. When I saw the bird again, it had dropped the snake at its feet and took flight when I came within 4 m of it. At this point I collected the snake, which was entirely limp with the exception of an occasional twitch of its head. The subcaudal portion of the snake was bloody, and there was a single wound at mid-body. These injuries were presumably inflicted by the bird's beak. Additionally, I noted a slight abrasion on the snake's head and assume that the bird had subdued its prey by thrashing it against the stonework.

The snake (AUM 35662) is female, 197 mm SVL, 225 mm TL, and 3.4 g. The Northern Mockingbird is characterized as omnivorous, and is known to take *Anolis* lizards (Derrickson and Breitwisch 1992 *In* Poole et al. [eds.], The Birds of North America, No. 7, Northern Mockingbird (*Mimus polyglottos*), pp. 1–26. American Ornithological Union, Washington, D.C. and the Academy of Natural Sciences, Philadelphia, Pennsylvania). I believe this to be the first record of ophiophagy by *M. polyglottos*.

Thanks to S. M. Boback, and C. Guyer for constructive comments.

Submitted by **GEOFFREY G. SORRELL**, Department of Biological Sciences, 331 Funchess Hall, Auburn University, Alabama 36849-5414, USA; e-mail: sorregg@auburn.edu.

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother 2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. SSAR Herpetol. Circ. 29:1–82, available online at <http://herplit.com/SSAR/circulars/HC29/Crother.html>; for Mexico as it appears in Liner 1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*. Herpetol. Circ. 23:1–113), LOCALITY (use metric for distances and give precise locality data), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author—curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Leviton et al. 1985, *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology*, Copeia 1985[3]:802–832) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief), SUBMITTED BY (give name and address in full—spell out state or province names—no abbreviations).

Some further comments. This geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens which have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality color slide or photograph may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Color slides and photographs *must* be deposited in a university or museum collection along with complete locality data, and the color slide catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary) to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extensions unless a thorough literature review has been completed.

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **Alan M. Richmond** (USA & Canadian records only); **Jerry D. Johnson** (Mexico and Central America, including the Caribbean islands); **Hidetoshi Ota** (all Old World records); or **Gustavo J. Scrocchi** (South American records). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Schmitz, A., and T. Ziegler. 2003. Geographic distribution. *Sphenomorphus rufocaudatus*. Herpetol. Rev. 34:385.

CAUDATA

AMBYSTOMA TIGRINUM MELANOSTICTUM (Blotched Tiger Salamander). USA: SOUTH DAKOTA: ROBERTS CO.: wetland adjacent to South Dakota Hwy 25, ca. 1.6 km W Hammer (45°50' 55.6"N; 97°02' 21.3"W). 8 September 2003. Laurs Bryan Williams. Verified by Stanlee Miller. Campbell Museum, Clemson University (CUSC 2167). County record. Previously reported in adjacent Marshall, Day, and Grant counties (Fischer et al. 1999. A Field Guide to South Dakota Amphibians. South Dakota Agric. Exp. Sta. Bull. 733. South Dakota State University, Brookings. 52 pp.).

HERPETOLOGICAL REVIEW

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2004 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with VISA or MasterCard (account number and expiration date must be provided). Payment should be sent to: Theodora Pinou, SSAR Treasurer, Peabody Museum of Natural History, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Fax: (203) 432-5176; e-mail: theodora.pinou@yale.edu

Future Annual Meetings

2004 — University of Oklahoma, Norman, Oklahoma, 26–31 May (with ASIH, HL)
2005 — University of South Florida, Tampa, Florida, 7–11 July (with ASIH, HL)

About Our Cover: *Coloptychon rhombifer*

There are six genera of anguid lizards in the subfamily Gerrhonotinae (Good 1988. Univ. California Publ. Zool. 121:1–139). They share several characteristics, the most distinct being an hourglass-shaped frontal bone and the most obvious being a lateral fold. They are called alligator lizards and they range collectively from the Pacific Northwest region of North America south to Panamá. There are about forty species, including some that are critically endangered, and some that rank among the most beautifully colored reptiles. Until recently, one of these, the Isthmian Alligator Lizard (*Coloptychon rhombifer*), was known from only three specimens. Not only is it surpassingly rare, but also it can reach half a meter in total length. Its habits and microhabitat are unknown. Understandably the Isthmian Alligator Lizard has assumed almost mythic proportions in the minds of field biologists. Now, 128 years after Peters named it, another has been found.

Alejandro Solórzano, one of Costa Rica's most active herpetologists and Director of its National Serpentarium, received a call from Golfito, a community in the southwestern part of the country. The caller had found a strange lizard wandering on the ground in his neighborhood and had put it into a cardboard box. Judging by the description of a long, snaky lizard with small limbs, Solórzano decided it might be *Coloptychon*. Elated at the luck, he set about organizing a trip to Golfito, but the lizard died before he could depart San José. He got lucky a second time because the caller informed him of the news immediately. Some biologists might have despaired but Solórzano saw opportunity.

Fortunately, the caller was willing to follow instructions to freeze the carcass in water. Solórzano retrieved the specimen and carefully defrosted it, taking care to relax the body thoroughly. He arranged the lizard meticulously toe-by-toe and took photographs, some for reference and some for aesthetics. He then extracted tissues for DNA analysis, retrieved the stomach contents, and carefully preserved the specimen. Ongoing studies will tell us more but we know the lizard had fed on an arthropod, and indications are that *Coloptychon* is basal to all gerrhonotines (J. A. Campbell, pers. comm.).

One of the most exciting things associated with this specimen is its size. It is a male, 505 mm in total length, nearly 50% larger than the known maximum. *Coloptychon rhombifer* is recorded from southwestern Costa Rica and adjacent Panamá, and the specimens have come invariably from moist, lowland forest. The tropics hoard their secrets, yet one wonders why no more of these impressive lizards have appeared. The region has seen botanical and zoological investigation for years. Is it simply because the Isthmian Alligator Lizard is rare? Could they dwell in the canopy? Do they live in burrows?

The long, likely prehensile tail makes an arboreal life seem possible, but the coloration is indicative of a terrestrial mode. Yet, if it is terrestrial one would expect more specimens to have turned up. It may be facultatively arboreal (H. Greene, pers. comm.) and there is anecdotal evidence from Costa Rica's Península de Osa that supports this contention. The scarcity of specimens may well indicate true rareness rather than something seen rarely by humans. The Isthmian Alligator Lizard remains an enigma, but Alejandro Solórzano's quick thinking has given the herpetological community a glimpse of a legendary reptile. He took the photograph under natural light using a Canon EOS Rebel with Canon 100mm macro lens on Fujichrome Provia film. Solórzano's book, *Snakes of Costa Rica*, will be published in a bilingual edition by InBio in March.

PHOTO BY WILLIAM W. LAMAR

Editor's note.—Special thanks to Bill Lamar for preparation of the foregoing text, and to Louis Porras and John Crawley (Focus Design, Inc.) for preparing Solórzano's image for publication.

SSAR BUSINESS

Announcing the 2004 Joint Meeting of Ichthyologists and Herpetologists 26–31 May 2004

The annual meeting of the Society for the Study of Amphibians and Reptiles, The Herpetologists' League, and the American Society of Ichthyologists and Herpetologists will be held 26–31 May 2004, hosted by the University of Oklahoma at the National Center for Employee Development/ Marriott Conference Center, Norman, Oklahoma (USA). Please refer to the Joint Meeting website (www.dce.ksu.edu/2004jointmeeting) for information on how to register for the meeting. All material normally included in the Call for Papers is now accessible on the Joint Meeting website. **In contrast to past years, the Call for Papers will only be mailed if requested**. Members who lack access to the internet may request paper copies from William J. Matthews, Department of Zoology, University of Oklahoma, Norman, Oklahoma 73019, USA (e-mail: wmatthews@ou.edu; fax 405-325-6202).

SSAR Election Results

Results of the 2003 SSAR election are as follows:

Board of Directors (Class of 2006)
.... David Hardy Sr., Richard Wassersug

Constitutional Ammendments
Article II, Section 1a: .... Approved
Article II, Section 3: .... Approved
Article III, Section 1: .... Approved

Thanks to all of the nominees who agreed to stand for positions and to Maureen Kearney (Elector).

NEWSNOTES

Kentucky Reptile Zoo Internships for 2004

The Kentucky Reptile Zoo, a nonprofit organization, is seeking student interns for the 2004 season. The zoo is an educational exhibit, reptile breeding, and venom research facility located near Kentucky's Red River Gorge and Natural Bridge State Park. The intern will assist in the captive maintenance of the zoo's reptile collection, collect admissions to the exhibit, give interpretive talks and interact with the public, assist with educational outreach programs, and perform other duties as assigned. In addition, the intern will be responsible for the completion of at least one research project related to the field of herpetology. The intern will **not** be involved in the handling of any venomous species.

Desirable qualifications include a willingness to handle snakes and other reptiles on a daily basis, ability to communicate effectively with people, writing skills, orientation to details, and self-motivation. The intern will be required to work Saturday and Sunday, with days off during the week. Students majoring in the biological or natural sciences are preferred. Interns are required to be either college students or recent graduates. Former interns have arranged for academic credit with their institutions. Benefits include experience with one of the most extensive and diverse collection of snakes in the United States, housing, and $55/week to cover expenses. Interns have been successful in finding zoo keeper positions; over 95% hire rate! Personal transportation recommended. Valid driver's license required. Starting dates are flexible, but a minimum of three months covering spring (April–June), summer (June–August), and fall (September–November) is required.

Deadlines are **February 1** for spring, **March 1** for summer, and **June 1** for fall. To apply, send a cover letter, résumé, transcript, and at least two (preferably three) references to: *Kristen Wiley, Internship Coordinator, Kentucky Reptile Zoo, 200 L&E Railroad, Slade, Kentucky 40376, USA or e-mail to: kyreptil@pop.mis.net.*

Biology of Boas, Pythons, and Related Taxa

A satellite symposium on the biology of boas and pythons is currently in planning stages for the 2005 SSAR meeting in Tampa, Florida. We must, however, have a list of contributors and tentative titles for presentations. The deadline for the proposal is prior to the SSAR meeting in 2004.

The main goal of the symposium is to exchange new information on the ecology, evolution, behavior, physiology, and conservation of boas, pythons, and related taxa. The format will be similar to the conference, **Biology of the Vipers**, held in 2000 at the Oldagården Conference Centre in Marielund, Sweden. Eagle Mountain Publishing, LC will publish a peer-reviewed book (*Biology of the Boas and Pythons*) that will follow the format of the recently published *Biology of the Vipers*. Editors will be Robert W. Henderson, Robert Powell, and Gordon W. Schuett.

At this time we are soliciting full-length manuscripts (book chapters) and color images (high quality slides or digital images) for the book. Manuscripts must be written in English and submitted in quadruplicate, including sets of figures and tables. In preparing manuscripts, authors should follow the general style of *Biology of the Vipers*. A formal guide for authors will be made available for accepted manuscripts. The editors are seeking original research and syntheses of important problems in the biology of members of Boinae, Erycinae, and Pythoninae, but also in the taxa *Xenopeltis*, *Loxocemus*, *Bolyeria*, *Casarea*, *Exiliboa*, *Trachyboa*, *Tropidophis*, *Ungaliophis*, and *Xenophidion*. No substantial portion of the work can be published or under consideration of publication elsewhere. Participation in the symposium does not guarantee manuscript acceptance. Conversely, manuscripts and/or slides intended for the book may be submitted irrespective of attendance at the symposium.

Please send manuscripts and slides/digital images to: *Robert W. Henderson, Section of Vertebrate Zoology, Milwaukee Public Museum, Milwaukee, Wisconsin 53233-1478, USA.*

Questions should be directed to Bob Henderson at rh@mpm.edu (voice mail: 414-278-2775; fax: 414-278-6100).

Kansas Herpetological Society Annual Meeting

The Kansas Herpetological Society held its 30th Annual Meeting at Emporia State University in Emporia, Kansas, on 8–9 November 2003. Over 90 participants attended scientific paper sessions to listen to 21 talks by scientists and students from across the nation. Featured speaker was Steven Beaupre, professor at the University of Arkansas in Fayetteville.

During the Society business meeting, Sean M. Daly, former graduate student at Emporia State University, received the 2003 Howard K. Gloyd/Edward H. Taylor Scholarship, honoring the memory of two great biologists with strong ties to Kansas. Dustin Wilgers, graduate student at Kansas State University, and James A. Daniel, graduate student at Pittsburg State University, received Alan H. Kamb Grants for Research on Kansas Snakes.

At the Saturday night auction and social, Larry Miller, Northern Hills Junior High School, Topeka, was chosen as the sixth recipient of The Suzanne L. & Joseph T. Collins Award for Excellence in Kansas Herpetology, based on his image of an Eastern Racer at Castle Rock selected as the best photograph of native Kansas herpetofauna.

MEETINGS

Meetings Calendar

9–10 April 2004—27th Annual All Florida Herpetology Event. Gainesville, Florida, USA. Information available at: www.flmnh.ufl.edu/herpetology/herpsconference/afhc.htm.

22–23 April 2004—Squamate Evolution and Systematics: A Conference in Honour of Garth Underwood. Linnean Society of London, UK. For information, contact: janet@linnean.org.

11–15 May 2004—Biodiversity and Management of the Madrean Archipelago II: Connecting Mountain Islands and Desert Seas. Tucson, Arizona, USA. Information available at: http://www.skyislandalliance.org/madreanconference/.

26–31 May 2004—47th Annual Meeting, Society for the Study of Amphibians and Reptiles, together with The Herpetologists' League and the American Society of Ichthyologists and Herpetologists. University of Oklahoma, Norman, USA. http://www.dce.ksu.edu/2004jointmeeting/.

10–13 August 2004—28th International Herpetological Symposium, Daytona Beach, Florida, USA. Information: http://www.kingsnake.com/ihs/.

15–20 November 2004—VI Symposium of Zoology, Topes de Collantes, Sancti Spiritus, Cuba. Information: www.geocities.com/zoologiacubana/simposio or by e-mail: zoologia.ies@ama.cu.

OBITUARIES

Herpetological Review, 2004, 35(1), 3.

Henri Cerét Seibert (1915–2003)

KRAIG ADLER
Neurobiology and Behavior, Cornell University, W342 Mudd Hall
Ithaca, New York 14853-2702, USA
e-mail: kka4@cornell.edu

Henri C. Seibert, who served SSAR and its predecessor, The Ohio Herpetological Society, in several official capacities for 28 years, died at the age of 88 on 6 October from complications following a stroke, in West Grove, Pennsylvania. Although he was an ornithologist by training and inclination, his professional career was spent in southeastern Ohio, an unglaciated, hilly region rich in salamanders which drew him more closely to herpetology and to an early association with the society.

Seibert (being French, his family pronounces it SEE-bert) was born in Caen in Normandy but emigrated to the USA and to Baltimore with his family at the age of six. He attended Haverford College (B.A. 1937 *cum laude* in biology) where one of his professors was the herpetologist Emmett R. Dunn. After a masters in human biology (1940) with Raymond Pearl at Johns Hopkins, he entered the doctoral program at the University of Illinois in 1941. Like several young biologists of his era, Seibert soon interrupted his studies to study the effects of radiation on living organisms as part of the then-secret Manhattan Project. He completed his dissertation in 1947 on the effects of photoperiod and temperature on weight and molt in birds, under the supervision of S. Charles Kendeigh and Victor E. Shelford. During the next years (1947–1951) he published several important papers on snake population biology in *Copeia*.

Henri C. Seibert, about 1958 (left); in 1992 (above).

After receiving his Ph.D., Seibert was appointed assistant professor of zoology at Ohio University in Athens, Ohio. He also became curator of the zoology department's vertebrate collections and served as department chair (1962–1967). The main courses he taught were herpetology, ecology, and ornithology. He supervised 23 masters students, among them two salamander biologists who went on to notable careers as amphibian researchers: Ronald A. Brandon and David M. Sever. It was with Brandon that Seibert published his major herpetological treatise, in 1960, "The Salamanders of Southeastern Ohio." His last herpetological contributions were species accounts in the book *Salamanders of Ohio*, edited by Ralph Pfingsten and Floyd Downs and published in 1989.

Seibert joined The Ohio Herpetological Society during its inaugural year, 1958. He soon became active in its affairs and by 1962 had become a member of the Board of Directors. One cannot overemphasize the importance of his joining the board at a time when most of the officers were college students. This was a generous and selfless act that was not without a certain professional risk. His reputation throughout Ohio immediately gave the young society credibility and a new status that helped it to expand its scope. Seibert's contributions to the organization's growth continued in many capacities, as Publications Secretary (1967–1976), Treasurer (1970–1987), and finally as President (1989).

As publications secretary, Seibert stored the society's rapidly-growing back stocks of journals and books. He personally handled all sales, which provided critical income to the society beyond dues and subscriptions and this allowed expansion of the society's program. As treasurer, he oversaw annual budgets that grew more than ten-fold, from about $8,000 to $90,000. At annual meetings of the Board of Directors, Seibert was always the final step in any discussion of new projects. "Henri, can we afford it?" He would reply, "We'll find a way to do it." He would simply adjust and re-adjust the proposed budget—adding here, subtracting there—until there were funds to cover the new project. He always tried to be a facilitator, not a roadblock. And so the society's publications, meetings, and other activities would grow, with a membership of 740 when he took over as treasurer in 1970 and 2257 when he stepped down 18 years later. When new members joined during any given year, it was Seibert who personally packed up all the back issues for that year and mailed them out. Seibert was instrumental in arranging for budding herpetologists and especially would-be members from overseas to join, by finding sponsors who could pay their initial dues costs. He carried on a voluminous correspondence with society members, answering questions, making referrals, etc. To many members, Henri Seibert *was* the society.

In gratitude for his long and dedicated service to OHS and SSAR, the society created The Henri C. Seibert Award in 1990 to recognize the most outstanding student papers presented at SSAR's annual meetings. His record of service to the society and thus to the development of herpetology as a discipline will be long remembered and honored.

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **Eli Greenbaum** or **Omar Torres-Carvajal**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Tuataras and the Phylogeny of Reptiles

Numerous hypotheses of higher-level phylogenetic relationships among reptiles have been suggested by previous analyses of morphological and molecular data sets. Depending on the study, the sister group of the genus *Sphenodon* has ranged from squamates to archosaurs and turtles. To examine the phylogenetic position of *Sphenodon* further, the authors sequenced the entire mitochondrial genome of *S. punctatus* and compared the data to homologous genes in other reptiles, mammals, and birds. A second analysis used *Sphenodon* as an outgroup to assess the phylogenetic position of snakes to other squamates. Genes for ND5, $tRNA^{Thr}$, and $tRNA^{His}$ were missing from the *Sphenodon* genome. The first group of analyses were performed on 14 taxa, either with or without the only snake *(Dinodon semicarinatus),* which has an unusually rapid rate of mtDNA evolution. The second analysis was limited to *Sphenodon* and six other taxa. Data were analyzed with Bayesian inference and maximum parsimony (latter method mainly for comparison); alternate trees were tested with the approximately unbiased (AU) and Shimodaira-Hasegawa (SH) tests. Lineage-divergence dates were assessed with truncated Newton optimization and calibrated with fossil data. The overall optimal tree from the first analysis placed tuataras as sister to squamates; eight of 13 alternate trees were rejected by the AU test, whereas three were rejected by the SH test. The second analysis placed snakes within the Anguimorpha (legless lizards + varanids) clade. Estimates of divergence times for major clades are discussed.

Rest, J. S., J. C. Ast, C. C. Austin, P. J. Waddell, E. A. Tibbetts, J. M. Hay, and D. P. Mindell. 2003. Molecular systematics of primary reptilian lineages and the tuatara mitochondrial genome. Molecular Phylogenetics and Evolution 29:289–297.

Sea Turtle Behavior and Habitat Use in Coral Reefs

Electronic devices have been used to study diving and migration behavior of sea turtles, but direct observations are preferred to minimize errors and provide improved data. The authors studied the foraging and diving behavior of hawksbill turtles *(Eretmochelys imbricata)* from five sites in the granitic Seychelles. Mock-up carapaces were used to estimate turtle size *in situ.* Observers tended to overestimate carapace size. A total of 51 turtles were observed in 120 h of monitoring; average size of these turtles was much smaller than adult nesting females. In general, turtles foraged at shallow depths (< 3 m) and rested at relatively greater depths (6–9 m). The absence of adult turtles from the study site might be explained by results of previous studies that documented continuous travel (3–5 days) of females after nesting. Relatively deeper dives by resting juveniles are probably a way to maximize resting duration.

Houghton, J. D. R., M. J. Callow, and G. C. Hays. 2003. Habitat utilization by juvenile hawksbill turtles (*Eretmochelys imbricata,* Linnaeus, 1766) around a shallow coral reef. Journal of Natural History 37:1269–1280.

Reproductive Behavior in *Edalorhina perezi*

Frogs often utilize small ponds, pools, or host plants for oviposition, but avoid sites where the risk of predation or competition to larvae is high. Murphy studied how site-choice behavior varied in a Peruvian leptodactylid *(Edalorhina perezi)* according to multiple risk factors, sex, and season. The author observed behavior in Manu National Park, Peru during the 1996–97 rainy season. Data were collected regarding male calling and female oviposition in three paired field experiments: 1) tadpole predators present or absent (repeated late in seven-month breeding season); 2) tadpole competitors present or absent; 3) tadpole predators or tadpole competitors present. Results suggested that males called more often at predator-free and competitor-free pools, although the latter result was not statistically significant. Females avoided pools with predators and competitors for oviposition. In general, both sexes favored pools with competitors to pools with predators. Late in the rainy season, females reproduced in control pools about as often as pools with predators. When restricted to low-quality sites, males called less frequently and females tended to delay oviposition. The change in female behavior during the latter part of the breeding season might be explained by impermanence of breeding pools.

Intraspecific Phylogeny and Historical Biogeography of a Salamander

Allopatric fragmentation and range shifts occurred as a result of global Pleistocene climate changes in many taxa. Two competing hypotheses (one dispersal, the other vicariance) have been proposed in previous studies to explain phylogenetic affinities of sev-

eral biota in the Central Highlands of North America. The authors tested these hypotheses by examining the intraspecific phylogeny of the ambystomid salamander *Ambystoma maculatum.* Samples were collected from 85 localities. Two mitochondrial gene regions (ND4-tRNA and control regions) were analyzed in PAUP* 4.0b4a with maximum parsimony (MP) and maximum likelihood (ML). Geographic and genetic structure was assessed with statistical parsimony and nested-clade analyses. MP and ML analyses resulted in concordant topologies. Two widely distributed lineages (interior and coastal clades) are consistent with two phylogroups identified in a previous study of this species. Genetic structure analyses suggested each lineage experienced fragmentation followed by range expansion and reduced gene flow in certain regions. Analyses in this study support a Central Highland dispersal hypothesis rather than a vicariance hypothesis.

The Oldest Known North American Colubrid

Present knowledge about the snake fauna of the Late Eocene is poor. The oldest known colubrids are documented from the Late Eocene in Thailand and Early Oligocene of North America, Europe, and Asia. The authors report a vertebra from the extinct genus *Nebraskophis* from the Late Eocene (36.0–34.2 Ma) of central Georgia, USA. Previous to this discovery, Asia had been noted as the most probable source for early colubrid evolution. However, because Georgian *Nebraskophis* were present in North America at the same time as the Asian colubrids, the origin of colubrids (in general) must predate the Late Eocene. The new discovery also bolsters evidence for a Cenozoic biogeographic connection between the Great Plains and the southeastern region of North America for colubrid snakes. The authors suggest *Nebraskophis* originated in southeastern North America (and not as a Eurasian immigrant), and then dispersed westward.

PARMLEY, D., AND J. A. HOLMAN. 2003. *Nebraskophis* Holman from the Late Eocene of Georgia (USA), the oldest known North American colubrid snake. Acta zoologica cracoviensia 46:1–8.

Spatial Overlap of African Tree Agamas

Female mate choice has been correlated with male territory quality and phenotypic characteristics in several species of lizards. The authors studied female *Acanthocercus atricollis* spatial patterns as they related to male and home range quality. Observations were conducted during the breeding season (September–November 2000) in Mountain Sanctuary Park, South Africa. Lizards were noosed, measured, weighed, marked, fitted with transmitters (in four cases), released, and observed with binoculars to minimize disturbance. Estimates of male mating success were determined from several factors that were analyzed in a Principal Components Analysis (PCA). In general, males had larger home ranges than females, male home range size was not correlated with male body condition, and female home range size was negatively correlated with SVL. Home range space was shared between males and females, but not among males. Results of the PCA suggest male quality, prey number, and tree size affect female overlap with male home ranges. It is difficult to separate the effects of male traits and territory quality on female mate choice and reproductive success.

REANEY, L. T., AND M. J. WHITING. 2003. Are female tree agamas *(Acanthocercus atricollis atricollis)* turned on by males or resources? Ethology, Ecology and Evolution 15:19–30.

A New Ancient Family of Frogs

Studies on the early evolution of neobatrachian frogs have been hampered by the dearth of Mesozoic fossils in this group. The authors report a new genus and species of burrowing frog from the Western Ghats in India. This frog, *Nasikabatrachus sahyadrensis,* shares some osteological characters in common with other neobatrachian frogs, but also has a unique combination of external and skeletal characters that suggest its recognition as a new family (Nasikabatrachidae). Skeletal and molecular data (2.8 kb of mitochondrial and nuclear DNA) identify the Seychellian Sooglossidae as the sister taxon to the new family. The finding supports the hypothesis that Sooglossidae were present on Indo-Madagascar during the Late Jurassic/Early Cretaceous and subsequently became extinct in India and Madagascar. The Nasikabatrachidae/Sooglossidae clade diverged before the split between India and the Seychelles at the Cretaceous/Tertiary boundary. Additional Cretaceous fossils are needed to understand fully the phylogeny and biogeography of early Indo-Madagascar neobatrachians.

Life History Characters of Amphibians

An understanding of amphibian life-history characters is the first step toward understanding global amphibian declines. The authors review patterns in life-history characteristics of amphibian populations at different geographic localities, including development and growth rates, body size, sexual maturity, length of breeding season, number of egg clutches produced annually, and clutch/egg size. In general, as altitude and latitude increase, breeding season length, number of clutches (per season), and growth and development rates decrease. However, body size, age at maturity,

clutch size, and egg size generally increase at higher altitudes and latitudes. Temperature seems to be the most important factor in these cases, but notable exceptions include competition, food, habitat permanency, and predation, especially for growth and development. Increased generation time and lower fecundity at high altitude/latitude amphibians make their populations more prone to extinction following a disturbance to their equilibrium. Because many declining populations have been noted from the tropics, altitude seems to affect amphibian life-history characteristics to a greater extent than latitude.

Ultraviolet Radiation and Amphibian Embryos

Increased levels of ultraviolet-B (UVB) radiation to Earth has been hypothesized to be a cause of global amphibian declines in numerous studies. Species that reproduce in aquatic areas exposed to direct sunlight are presumed to be most at risk, but several factors can reduce this risk and include: 1) water color and depth, which attenuate UVB; 2) melanin of eggs that block UVB; 3) photolyase, which can repair DNA damaged by UVB; and 4) egg capsules that absorb UVB. Licht discusses previous studies that demonstrated the effectiveness of the above four factors to prevent UVB damage to amphibian embryos. Because some protection is lost upon hatching, post-hatching and larval amphibians are relatively more sensitive to UVB radiation. However, they possess increased mobility and can move to areas shaded from direct sunlight, which decreases the importance of studies that restricted the movement of larval amphibians exposed to artificially high levels of UVB radiation. Numerous studies have cited detrimental effects to embryos, but experimental conditions often did not account for natural circumstances that shielded eggs from UVB exposure (e.g., laying eggs on the underside of rocks). Moreover, some studies used acetate filters, which are known to be toxic to hatchling amphibians. Licht concludes that realistic environmental factors are not sufficient to link UVB radiation and amphibian population declines.

Apateon and the Origin of Salamanders

Because of large gaps in the fossil record, the origin and interrelationships of Lissamphibia (frogs, salamanders, and caecilians) remains a contentious issue. Three major hypotheses are currently debated in the literature: 1) a monophyletic Lissamphibia originating from temnospondyls; 2) a monophyletic Lissamphibia originating from lepospondyls; and 3) a diphyletic origin of Lissamphibia with caecilians allied to lepospondyls, frogs with temnospondyls, and salamanders related to either lepospondyls or temnospondyls. The authors argue that lepospondyls (larvae absent in fossil record) are not likely to be ancestors of frogs and salamanders, both of which possess gilled larvae among their primitive members. However, temnospondyls have extraordinarily well-preserved ontogenetic series represented in German Carboniferous fossil beds (e.g., *Apateon caudacus),* which makes comparisons to modern Lissamphibia larvae possible. The authors compared the sequence of ossification of the dermal skull in *A. caudacus* with extant hynobiid, ambystomid, and salamandrid salamanders. Numerous similarities were documented, and the authors suggest that modern salamander skulls could have evolved by terminating ossification prior to formation of the circumorbital bones, which distinguish most Paleozoic amphibians.

Molecular Phylogeny of Pelobatoidea

The monophyly and phylogenetic relationships of primitive frogs included in Pelobatoidea and their relationships to other anurans have been debated in several previous studies. To address this problem, the authors sequenced 520 bp of 16S and 385 bp of cyt *b* for most species of Pelobatidae and Pelodytidae, *Leptolalax pelodytoides, Brachytarsophrys feae,* and *Megophrys lateralis;* outgroups from every major clade of frogs were included in the anlaysis. Phylogenetic analyses (maximum parsimony, maximum likelihood, and Bayesian) were performed independently and on the combined data sets in PAUP* and Mr. Bayes 2.0. ML and Bayesian analyses produced trees with identical ingroup topologies. Pelobatoidea formed a monophyletic group, as did all genera examined. Relationships among genera were not consistent with previous hypotheses; monophyletic Pelodytidae and Megophryidae were supported, but not Pelobatidae. The authors suggest fossoriality evolved independently in Scaphiopodidae and Pelobatidae.

García-París, M., D. R. Buchholz, and G. Parra-Olea. 2003. Phylogenetic relationships of Pelobatoidea re-examined using mtDNA. Molecular Phylogenetics and Evolution 28:12–23.

A Morphological and Molecular Phylogeny of Emydid Turtles

Currently, the turtle family Emydidae contains 40 species in 10 genera. Previous phylogenetic studies of this group agreed on recognition of two subfamilies (Emydinae and Deirochelyinae), but numerous other conflicts remained. The authors combined 237 morphological characters and 547 parsimony-informative characters (cyt *b,* control region, 16S, and ND4 genes) for 39 of 40 emydid species to conduct a comprehensive phylogenetic analy-

sis. Parsimony analyses of morphological data, and maximum likelihood (ML) and equally weighted parsimony analyses of molecular data were conducted in PAUP* 4.0b1. Four hypotheses of ecological diversification were explored within the context of the resulting phylogeny from the combined analysis of morphological and molecular data sets. Results supported the monophyly of Emydidae, both emydid subfamilies (in most cases), and the majority of ingroup genera. Overall, results support a "limited-diversification hypothesis" of ecological diversification, which argues against simultaneous changes on one or more ecological axes. The authors propose that recent speciation events in emydids have been a result of allopatric speciation between ecologically similar taxa.

Stephens, P. R., and J. J. Wiens. 2003. Ecological diversification and phylogeny of emydid turtles. Biological Journal of the Linnean Society 79:577–610.

Systematics of North American Chorus Frogs

Frogs of the genus *Pseudacris* are distributed from the southern tip of Florida to northern Canada along both coasts of North America. The authors examined the phylogenetic relationships of 38 populations of *Pseudacris,* representing 23 of 28 known species and subspecies. Approximately 2.4 kb of a mtDNA region (incorporating 12S, tRNAval, and 16S rRNA) was sequenced for each taxon; maximum parsimony, maximum likelihood, and Bayesian analyses were performed. A published allozyme dataset was re-analyzed to calculate Manhattan distances between taxa. Results of the mtDNA analyses identified four major clades within a monophyletic *Pseudacris:* (1) West Coast Clade (*regilla* and *cadaverina);* (2) Fat Frog Clade (*ornata, streckeri,* and *illinoensis);* (3) *Crucifer* Clade (*ocularis* and *crucifer);* and (4) Trilling Frog Clade (all remaining species). The mtDNA phylogenetic hypothesis is mostly incongruent with those of the re-examined allozyme dataset, and other published allozyme, morphological, and behavioral datasets. Geographic boundaries of some *Pseudacris* species are difficult to determine because of broad sympatry with other taxa, hybridization, and dearth of clearly diagnostic characters; some currently recognized distributions are not consistent with the results of this study. The taxonomic status of some species and subspecies are discussed.

Moriarty, E. C., and D. C. Cannatella. 2004. Phylogenetic relationships of the North American chorus frogs (*Pseudacris:* Hylidae). Molecular Phylogenetics and Evolution 30:409–420.

Roger Conant (1909–2003)

Roger Conant passed away in the early morning hours of 18 December 2003 in Albuquerque, New Mexico, at the age of 94. A full obituary will appear in the June 2004 issue of *HR*.

ZOO VIEW

Carl F. Kauffeld (1911–1974) at the Staten Island Zoo in New York was a pioneer zoo herpetologist and his influence on many in the profession has been considerable. He started as Curator of Reptiles in 1936 and began building the reptile collection. Kauffeld became Zoo Director in 1963 and retired a decade later. The rattlesnake collection was world famous; the collection reached 34 forms in 1963.

Some of his publications listed below will give a sense of his importance to captive management and husbandry. His inspirational writings of collecting adventures throughout the United States at his favorite sites such as Okeetee Preserve in South Carolina, Ajo Road and Ramsey Canyon in Arizona, and Lake Okeechobee and Payne's Prairie in Florida were the impetus needed for enthusiastic collectors to hop in their cars and speed quickly to these places.

Kauffeld's importance to his zoo has been described in detail in a new book by Ken Kawata, general curator, called *New York's Biggest Little Zoo. A History of the Staten Island Zoo*. This is a loving treatment, filled with anecdotes about the history of the Zoo, Kauffeld's unique personality and remarkable career, and Patricia O'Connor, the first full-time woman zoo veterinarian in the United States. I recommend it highly, the perfect read for a quiet afternoon.

BOOKS OF NOTE

In 2002, R. Frankham, J. D. Ballou, and D. A. Briscoe published "Introduction to Conservation Genetics" (Cambridge University Press, Cambridge), an exceptional book summarizing the history of genetic management. Jonathan Ballou is a population biologist at Smithsonian National Zoological Park (SNZP). Twenty-three years earlier, Jon and his colleagues published a landmark paper on inbreeding and juvenile mortality in small populations of ungulates (1979. Science 206:1101–1103) which has led to a major change in the captive management of zoo animals.

Elliott Jacobson, veterinary pathologist at the University of Florida, has edited a book on green iguanas (2003. Biology, Husbandry, and Medicine of the Green Iguana. Krieger Publishing Co., Malabar, Florida 2003) which includes chapters by zoo workers. Allison Alberts and John (Andy) Phillips from the Center for Reproduction of Endangered Species at the San Diego Zoo in California and Nancy Pratt-Hawkes from Disney's Animal Kingdom in Lake Buena Vista, Florida describe the ontogeny of captive and wild iguanas by focusing on hormonal, morphological, and behavioral changes from birth to first reproduction. Mary Allen and Olav Oftedal from SNZP cover nutrition in captivity, based in large part on research conducted at the Zoo. They evaluate the quality of commercial diets, importance of ultraviolet light, and recommend nutritionally balanced diets. Frederick Antonio, general curator at the Central Florida Zoological Park in Lake Monroe, joined several other authors in outlining husbandry and management protocols. Kelly Helmick from the El Paso Zoo in Texas coauthored a chapter on drug dosages and chemotherapeutics.

In the new SSAR book "Islands and the Sea: Essays on Herpetological Exploration in the West Indies," Allison describes her experiences working with the reptiles of Guantanamo Bay, Cuba. Retired curator Richard Sajdak from the Milwaukee County Zoo details his experiences in studying vine snakes (*Uromacer*) on Hispaniola in 1980. Charles Knapp from the John G. Shedd Aquarium in Chicago writes about his work with iguanas (*Cyclura*) in the Bahamas.

"HOWEVER, I BELIEVE THAT HERE IT MUST BE ATTEMPTED TO PRESENT EVERYTHING FOR EVERYONE, AND THERE ARE PROBABLY ENOUGH READERS WHO, ATTRACTED BY SUCH A BOOK, WILL WANT TO SEEK THE PLEASURE OF OBSERVING AN AMPHIBIAN [HERE INCLUDING REPTILES] AND A FISH, YEA, EVEN AN INSECT OR A WORM WHICH CAN TOLERATE THE AIR IN A ROOM, AND WHO ENJOY THE STUDY OF NATURE."

TRANSLATED FROM JOHANN MATTHÄUS BECHSTEIN (1797)

Johann Matthäus (or Matthaeus) Bechstein was born on 11 July 1757 in Waltershausen in Thuringia (today, part of Germany) and was interested in nature at an early age. He studied at the "*Gymnasium Illustre*" in Gotha, where languages and natural science, physics and mathematics were taught. After completing his studies at the *Gymnasium* he studied theology from 1778 to 1781 at the University of Jena. Four years later, he taught mathematics and natural history in his native Schnepfenthal, but focused on teaching forestry after 1793. After Bechstein completed a public examination in the spring of 1795, conducted by senior forestry master Friedrich August Ludwig von Burgdorf (1747–1802) at the Forestry School in Berlin, he founded a private re-

FIG. 1. Portrait of Johann Matthaeus Bechstein. Courtesy of Kraig Adler.

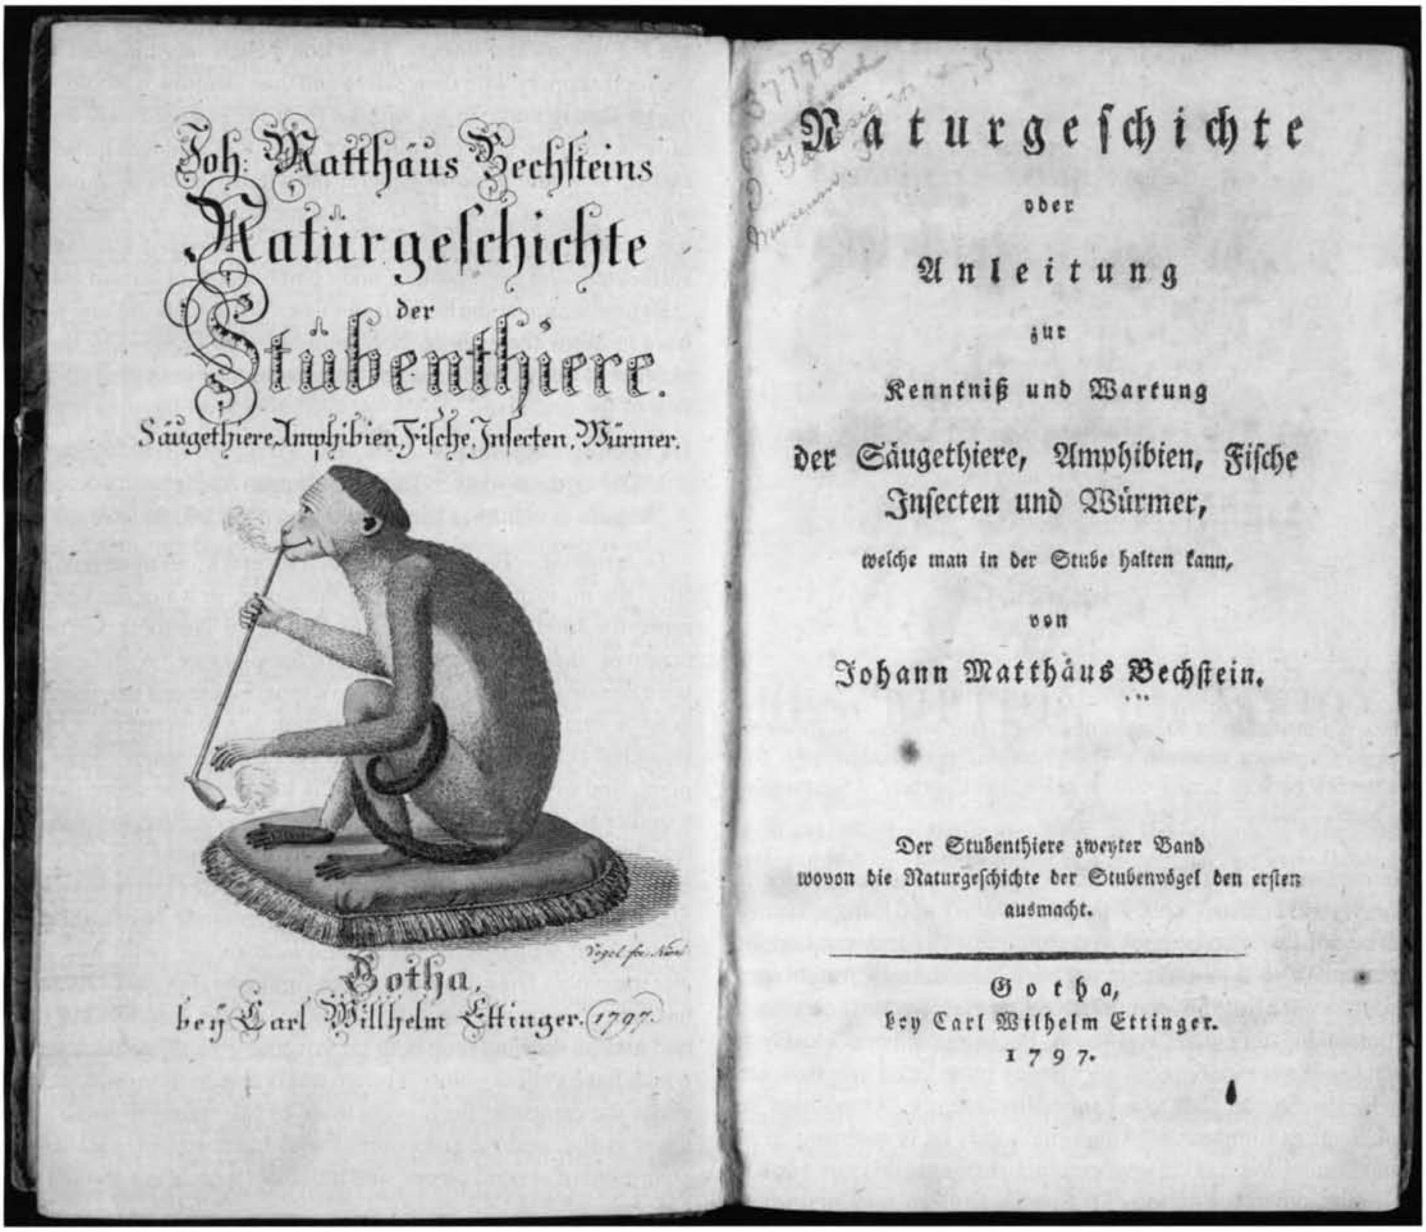

FIG. 2. Engraved title page and printed title page of "Naturgeschichte; oder, Anleitung zur Kenntniss und Wartung der Säugethiere, Amphibien, Fische, Insecten und Würmer, welche man in der Stube halten kann" by Johann Matthaeus Bechstein in 1797. Courtesy of Smithsonian Institution Libraries, Washington, DC.

search institute and the "Society for Forestry and Hunting Lore" in Waltershausen. Because of insufficient financial support, his institute closed in 1799. That year Duke Georg von Meiningen installed him as forestry councilor with the purpose of creating the forestry school in Dreissigacker; it was opened in 1801 and elevated in 1803 to the status of a forestry academy. In 1806 the University of Erlangen bestowed on him the degree of a doctor of philosophy. Bechstein died 23 February 1822 in Dreissigacker bei Meiningen, Thuringia.

Bechstein was a prolific author and some of his translated titles are as follows: "Natural History of Germany for the Common Use in all Three Kingdoms" (published between 1789 and 1795); "Natural History of Birds for the Home" (1795); "Natural History or Guide to Knowledge and Care of Mammals, Amphibians, Fishes, Insects and Worms which can be Kept at Home" (1797); translation of the Natural History of the Amphibians by B. G. E. de Lacepéde under the title "Mr. de la Cepede's Natural History of the Amphibians or the Oviparous Four-legged Animals and the Snakes—a Continuation of Buffon's Natural History (1800–1802)," in five volumes; and "The Science of Forestry and Hunting in all its Parts" (32 volumes between 1818 and 1835). His book "Cage and Chamber-Birds, Their Natural History, Habits, Food, Diseases, Management, and Modes of Capture" was translated from the German in 1864.

Bechstein's book on captive care of reptiles and amphibians was entitled "Naturgeschichte; oder, Anleitung zur Kenntniss und Wartung der Säugethiere, Amphibien, Fische, Insecten und Würmer, welche man in der Stube halten kann." In it, he covered five herp taxa: European pond turtle (*Testudo orbicularis*, now *Emys orbicularis*), common tree frog (*Rana arborea*, now *Hyla*

FIG. 3. Illustration of common tree frog (*Hyla arborea*) in Reverend Gregory Climenson Bateman's "The Vivarium," published in 1897. This was the first book on herpetoculture in English. Courtesy of Smithsonian Institution Libraries, Washington, DC.

arborea), sand lizard (*Lacerta agilis*), great crested newt (*Lacerta palustris* and *lacustris*, now *Triturus cristatus*), and European grass snake (*Coluber Natrix*, now *Natrix natrix*). The terms aquarium, terrarium, or vivarium had not yet been coined, so Bechstein used descriptors like little boxes, buckets, sugar glasses, containers made of porcelain, stoneware, and so on. Bechstein adheres closely to the rules of systematic zoology already introduced 40 years earlier by the Swede Carl von Linné. Bechstein's "Amphibien" is equivalent to Linnaeus's "Amphibia"; thus he is referring to all herpetofauna. We had the opportunity to examine this rare book in the Smithsonian Institution (SI) Special Collections Department of the Joseph F. Cullman 3rd Library of Natural History and an English translation of the section called "Amphibien" is provided below.

TRANSLATION OF "AMPHIBIANS, WHICH MAY BE KEPT IN THE HOUSE"

Introduction.—There are also amphibians which the amateur can keep in his room for his pleasure; to be sure, in contrast to birds and mammals, only very few. Also, they offer the pleasure not for long and are kept mainly because of their rarity or beauty; a few show some capacity for training, and only the tree frog is raised to serve as weather prophet.

Generally speaking, the exterior of the amphibians—even of the most beautiful forms and colors—has something repellant and suspicious about it so that they must be struck from the list of beautiful and inviting creatures. However, this results usually from an error in upbringing as careful observations show.

The characteristics of these animals differs in the wild, therefore also in the room, since some live in dry climates, others in the water; thus there is a difference also in the home, and since they are few in number, it is best to describe each animal in a few words. Just as different as their environment is also:

The nourishment of the household amphibians. Most of them are fed worms and insects. They don't chew anything but make the food slippery with their saliva and then swallow it whole. They digest slowly and can go without food for extraordinary lengths of time because they perspire very little. It is said that turtles can fast for a whole year. In general the vitality of these animals is admirably great, so much so that some still live after their heart has been ripped out; some die only very slowly if they are not suffocated, and even replace body parts cut off or almost lost.

Reproduction in the home is unthinkable; in that case one would have to allow the eggs of these animals to be brooded by the sun in order to discover the step-by-step development toward completion of the organism.

I. Crawling Amphibians

1. The Ordinary River Turtle (European Turtle)
[*Testudo orbicularis* Lin., now *Emys orbicularis*]

Description.—People usually keep several kinds of turtles, even from the most distant regions of the world, in water buckets, but more for food than pleasure. In Middle or Northern Germany, however, these are kept preferably for pleasure. With head and tail extended, the animal grows to a length of about one foot. The head is small, and when it is retracted, it is covered by a black, wrinkled skin which seems to form a cap. The snout comes to a point, and even though the mouth is toothless, the sharp jaws fit together so perfectly that the animal is thus enabled to crush and tear apart its food. The tail is relatively long, round and gradually ends in a point; while the feet are webbed, they clearly have toes. Such turtles are called *river turtles* to differentiate them from other families, of which some are named *land turtles* (with true toes) and the others *sea turtles* (with feet similar to flippers). Our turtle has four toes (aside from the webbing) on the fore feet but only two toes on the hind feet; both are covered with shiny black scales which have yellow points. The animal is able to hide head and tail under the carapace; for it is enclosed in two roundish shells. The lower is flat, yellow, and covered with black stripes; each one is composed of several pieces, and the edges thereof are smooth and not serrated.

Sojourn

a) At liberty: This turtle is encountered in the southern and moderate parts of Europe. It is but rarely found in Germany. It lives in fresh water on the bottom in the mud and spends the winter asleep.

b) In captivity: They are placed either in small ponds in gardens, or in the house and courtyard in buckets.

Nourishment

a) At liberty: They feed on water insects, snails, and foliage, etc.

b) In captivity: Here one can feed them for long times with bran, flour, bread, and other remnants from the kitchen.

Reproduction

They lay hard-shelled eggs similar in size to pigeon eggs and bury them in the ground.

Capture

They are fished with a net from the fresh water mud.

Commendable Characteristics

It cannot be said that their movements are varied or beautiful, or that these animals may be counted among those which are en-

tertaining; however, their very rarity, and the desire to have something alive also from this class of animals under one's care and supervision makes them attractive to the amateur. They can also be fattened up so as to make use of their tasty (even though hard to digest) meat, once the eyes have been satisfied by their sight. Already clever experiments have been made with these animals: Mr. Merz in Paris shut the mouth of one with wire and closed up the nostrils with sealing wax; nevertheless the animal lived another 30 days without food or breathing. This reveals the tenacious vitality which these animals possess.

2. The Tree Frog (Ordinary Tree Frog)
[*Rana arborea* Lin., now *Hyla arborea*]

Description.—This pretty little frog, which is particularly attractive because of the rare cleanliness of its skin, its coloration, and the delicate body structure, measures about 1.5 inches[1] in length. The upper body is green; the lower parts yellowish-white. The latter are covered with small raised warts which are nothing other than glands containing a caustic fluid; if you catch a tree frog with bare hands and then touch your eyes without first washing them (which happened to me frequently) this moisture irritates painfully for a long time. In complete condition the green color of the body is grass-green; however, once the mucous skin has been shed—as these amphibians frequently do—the body color changes to blackish or dark reddish-gray with white spots and thereupon becomes yellowish-green and is separated from the lighter lower body by a light yellow stripe with brown edges. We recognize the males by their yellowish throat which, when they croak, they blow up into a round bubble nearly as large as the entire body. Instead of nails, the toes bear little plates shaped like shields which enable them to attach themselves to the underside of leaves and to glass.

Sojourn

a) At liberty: During the summer we encounter this little frog on shrubs, trees, in the grass and in grain. When the sun is shining, they hang from the underside of leaves. In the fall they wander into ponds and swamps and mate there until June, and then climb up again to the trees and shrubs. During the evenings in May and June we can hear over a distance of half an hour the timorous croaking from the swamps where these animals mate in innumerable quantities. From far away this sounds like the ringing of sled bells.

b) In the room: The animals are placed in the window—but in such a way that they are not exposed to direct sunlight—in water glasses equipped with a small ladder and tied at the top with paper with holes in it, or they are put in clear wire cages laid out with moist sod or grasses. Both the water in the glasses as well as the sod and grass in the cages must be changed from time to time so that these little creatures can feel well.

Nourishment

a) At liberty: Here they catch with amazing speed flies and other insects from the leaves of trees, bushes, and weeds and grasses.

b) In the room: There they are given from time to time a living fly. However, they hesitate to touch dead insects.

Reproduction

These frogs sometimes mate for as long as three days. Like all our frog species, the female lays small eggs; these first develop into tadpoles without, and later then with feet; finally the tail falls

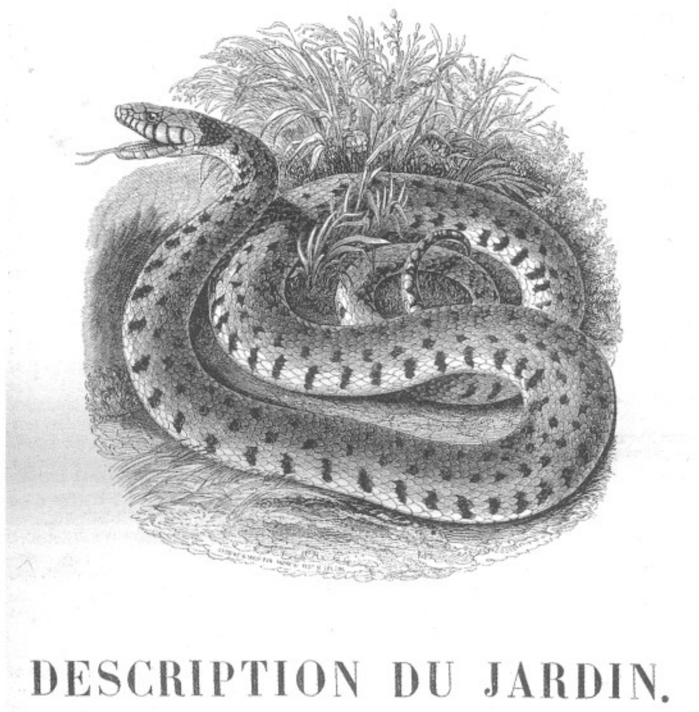

FIG. 4. Illustration of common ring-snake of Europe (*Natrix natrix*) in M. Boitard's "Le Jardin des Plantes. Description et Moeurs des Mammifères" in 1845. Courtesy of Smithsonian Institution Libraries, Washington, DC.

off, and the small, graceful little tree frog is complete. The animal remains in the water until full development; only as a true frog it climbs up on trees and shrubbery.

Commendable Characteristics

We usually employ the frog as weather forecaster. It announces changes in the weather a considerable time in advance; preferably through loud crowing and croaking. Also, when rainy or otherwise bad weather is about to occur, it goes into the water and behaves there in a restless manner; when the frog anticipates pleasant, dry weather, it climbs to the higher region of the glass or up the ladder. Its croaking makes it rather unpleasant.

3. The Green Lizard
(Common Lizard, Copper Lizard, Leaper)
[*Lacerta agilis* Lin.]

Description.—A commonly known, very agile and beautifully marked animal. It measures between 5 and 10 inches. Its color varies. As a rule they should be of golden hue on top, with brown and black spots on the sides, and copper-colored or yellowish-white on the lower body. The scales on the throat are longer than the norm and more pointed, and they form kind of a double necklace; the shields on the belly are square; the thick hind legs bear a row of horny warts, and the long tail is ringed and sharply scaled. In catching these animals, it is necessary to proceed with caution so as not to injure the tail which breaks so easily. The tail also possesses great reproductive power, for if it is cut off, a new one grows, albeit very incomplete. The feet have five toes with sharp nails.

Sojourn

a) At liberty: These lizards inhabit the warmer climates of Eu-

rope as well as both Indies and the South Sea islands. The further south they are found, the larger, more colorful and more beautiful they are. They remain in the forested regions, and in gardens, walls and rocks which are found in such regions. In the summertime they seek a cave under a shrub, root, or stone; in the winter they retreat further into holes, especially in dense shrubbery and in hedges where they are covered by a heavy blanket of leaves and grass.

b) In the house: Here one may either allow them to run around freely by setting a small box into a corner equipped from time to time with moist substrate and makes sure that they don't escape from the room by the door. Normally one places them into a wide sugar glass and adds moist moss and soil.

Nourishment

a) At liberty: Flies and other insects, worms, snails, small frogs, and other little lizards, even of their own species. In front of low beehives they often also prey on bees in the sunshine.

b) In the room: They may be given only one of the above-named foods in order to maintain them for a long time; even if they are only occasionally given a fly, they are content.

Reproduction

The female lays eight and more dirty white, blunt-round eggs, which shine for a while in the darkness under the rocks, often in the midst of large black ants which, however, do not attack them. The young are brooded by the warmth of the sun, with each egg containing only one animal, hatch in August and even as late as September; for two years they look green and multicolored brown.

Positive Properties

It is only a matter of becoming accustomed to the sight of these: Like all amphibians, we will undoubtedly find them appealing and beautiful. They are also distinguished by exceptional vitality, speed, and alert appearance. Finally they get to know the amateur, and he is able to play with them as with other animals in the house. These animals also lead us to admire the great reproductive force of nature, as entire limbs grow anew (even if not completely). It is also noteworthy that this harmless little animal has the characteristic to reveal the most subtle and concealed poison of the animals from this class in that it dies with cramps of the whole body if it has been bitten by another.

4. The Marsh Salamander
(Water Salamander, Water Newt, Water Lizard)
[*Lacerta palustris* and *lacustris* Lin., now *Triturus cristatus*]

Description.—The appearance of these animals is not exactly appealing; yet they can be kept easily in a glass in the room, often changing the water, and occasionally throwing in a fly as nourishment. The reproductive urge of these animals is notable by such phenomena: as soon as they are placed in a larger vessel, their gentle motions in swimming and the flatteries and caresses exchanged by males and females. Usually we don't know these animals well enough and mistake males, females, and young for different species. Hence I want to describe them somewhat more specifically:

Males: The length measures five inches from the tip of the mouth to the end of the tail. Up to the ears the head measures 1/2 inches, flat on top, rounded bluntly in front, blown up on the cheeks; the round nostrils are located in front, far distant from each other; the eyes are large, the iris golden-yellow but divided by a dark-brown circle so that it appears to consist of two rings. The eyebrows are raised. The eyes are closer to the mouth than to the ears. The raised skin back seam begins between the eyes and ends on the hind feet; it is serrated in the shape of a saw, most profoundly in the middle of the back, most finely at the end of the back and in the neck; between the hind feet one feels only the seam without the skin; the raised skin begins again with the tail, but it is bluntly serrated. This skin can float and adheres again immediately when the animal is not in the water but looks beautiful in swimming. The front feet have four toes with two spheres [dumbbell-shaped phalanges]; small warts and dull points, and the back five also with such round warts and points. The forelegs measure 3/4 inches to the toes, and the hind ones are almost 1 inch long. The entire upper body and the sides are covered with small raised warts; the lower body more with fine seams and furrows. The upper body is dark-olive green; from a distance it looks black, with isolated, catered black spots. The sides begin at the lower jaws; they are black with fine white points. The lower body is orange-yellow, on the chest from the vent and on the sides large black spots with all kinds of longitudinal figures. The throat and the soles of the feet are light yellow; the form spotted dark brown and spotted in white and can be blown up to a large size; the pointed half of the toes are also yellow with black bands. Other than that, the feet are like the upper body: The broad tail is shaped like a lancet, has a yellow spot behind the vent, is olive-brown above and below with white points on the sides of the root; nearly in the center marked on both sides with a bluish-white stripe which becomes pure-white after the point. In the water appears beautifully light, almost transparent.

The female is larger than the male by nearly one third, with a length of 7.5 inches; the head is somewhat thicker and engorged, especially at the point; the entire body somewhat thicker and more plump, especially in April and May, when the belly contains eggs; the color of the back is somewhat lighter, hence the black points are more prominent; the lower body is of a beautiful orange-yellow color and also marked with beautiful broad black spots of various shapes and forms; this yellow color continues uninterrupted to the tip of the tail. The serrated back skin is missing, and only the tail has several flat notches. The blue-white center stripe is not clearly visible because in fact it is mixed in a dirty-dark-ash-like manner with the other colors. The bands above the toes are not visible everywhere; other than that, everything is the same.

As for the two-year-old male, 2.5 inches long, the back skin starts in the neck and is dull; the upper body is olive-green, beautifully spotted with black and olive-brown spots; from the top and the sides the head has similar stripes; the throat is dirty-white with olive-brown spots; the remaining lower body has the color of egg yolk all the way to the end of the tail with isolated similar round spots. The narrow blue-white stripe runs along the sides of the yellow lower underbody. In relation to the adult (older) male the tail is somewhat broader, and the toes of the hind legs are also somewhat broader; the points of the front foot toes are black, and the legs are only vaguely formed.

The two-year-old female, somewhat exceeding the above-described male in size, matches the older female in every detail but deviates strongly in color; for this reason it is often taken for a different species. The upper body is olive green with a fine dark-brown line along each side of the back; throat, sides and legs are

dirty-yellow; the belly butter-yellow.

Oddities

In April and May the females lay their eggs in the water, where old and young permanently stay; especially in stagnant swamps, ponds, and fountains. At times these eggs are of a jelly- or glasslike consistency containing the white-yolk-looking like a white radish seed.

These animals feed on flies and on all manner of water insects; they do not inflict the great damage on the fish harvest of which they are accused; they prefer to eat their own brood rather than fish. In the spring, when one fishes muddy ponds, especially in forested areas, one can catch these animals in large quantities.

II. Crawling Amphibians

5. The Ringed Snake (House Snake)

[*Coluber Natrix* Lin., now *Natrix natrix*]

Description.—This is the most common native species of snake, and completely harmless; for this reason one may see swindlers walk around with them; they put them in their mouths and cause them to perform all manner of tricks under the pretense that these are poisonous snakes which they are able to control in such a way that they can do no harm. I have seen them at a length of four feet and longer. The female is always larger and thicker than the male. Normally one counts 170 broad belly plates and 60 ventral tail scales but the number is not so exact. The upper body is either blue-green, iron gray, or rust-gray; on the sides spotted in white with individual blackish points; the lower body is black, with white interruptions along the sides and under the belly so that it gives the impression of having black stripes. On both sides of the neck the male has a yellow spot and the female a whitish-yellow spot in the shape of a necklace or neck ring; hence the name.

Sojourn

a) At liberty: We find them in the highest mountains as well as the lowest valleys, in dry as well as swampy places—in places where they can never enter the water as well as sites where they can swim daily in the water, on the banks of ponds and rivers. Usually they seek out shady spots because they love the warmth of the sun only at certain times, e.g., when they have shed the old skin. They like to stay in stables, cellars, and garbage dumps.

b) In the house: In the room one allows them to run around and gives them a little box with wheat bran where they go to sleep.

Nourishment

a) At liberty: Their food consists of toads, frogs, lizards, snails, mice, worms, etc. Often I have cut open a snake which had swallowed a frog, and the frog jumped out again.

b) In the house: In the room the snake is content with milk and wheat bran.

Reproduction

The ringed snake deposits its eggs in compost beds, garbage dumps, stale places in stables. The gray-white-skinned eggs are linked together like pearls. At mating time the male and female exude an unpleasant odor, some say like a billygoat, but I cannot agree; I find it a unique, sweetish odor. Each egg contains one young the length of a finger when it hatches and looks cute.

Capture

They can be caught anywhere, especially when they are young when they also look their best—in compost heaps, also the heaps of garden trash which are raked together in the spring in gardens and meadows. Here they are often found by the hundreds.

Positive Properties

These are certainly endearing animals which can be trained to dance with a stick and the pipe, and to play dead.

My friend Mr. D. Vognetz has a ringed snake which is so tame that she crawls up and down in the room like a domestic bird, often climbs up on him, crawling up the arms and into the bosom. But it does not easily approach anyone else. He puts it in his pocket, goes into the garden with it and as soon as he emits a loud whistle, similar to the tone with which at mating time they call their mates, it comes to him, crawls up on him, lets him put it in his pocket and remains there without moving until he takes it out again. Since these crawling amphibians often grow exceptionally large, this has provided opportunity for all kinds of fables.

They can go for long periods without food but also grow extremely slowly.[2]

Footnotes:

[1] The old German Zoll, translated here as inch, seems to have been slightly longer than the American inch, but we have not been able to determine the exact ratio. - Translator

[2] It is also possible to tame the common viper (*Coluber berus*, now *Vipera berus*) and at times to remove their venom by letting them bite a cloth or piece of leather, so that it does not easily damage its master who feeds them. But I advise against it because one can never be sure; hence I also have not added a description.

Acknowledgments.—In 2001, Werner Rieck wrote a comprehensive biography of Johann Matthäus Bechstein and much of our material on his life and importance to the history of maintaining captive amphibians and reptiles is excerpted from that publication.

Smithsonian National Zoological Park Librarian Alvin Hutchinson was instrumental in arranging a meeting with Leslie Overstreet and Daria Wingreen of the Joseph F. Cullman 3rd Library of Natural History from the SI Special Collections Department so that we could see Bechstein's book. Judith Block and Kraig Adler reviewed early drafts of this manuscript. We are indebted to the staff of SI Behind-the-Scenes Volunteer Program, especially Amy Lemon, for courtesies extended to us. Dale Miller from the SI Office of Imaging and Photographic Services provided the image of the title page from Bechstein's book.

Studies of field behavioral endocrinology permit researchers to examine the relationship between hormones and an organism's behavior under natural conditions. For analyses of circulating steroid hormones, blood harvested in the laboratory is typically centrifuged immediately to obtain plasma, which subsequently is stored frozen (e.g., ultra-low freezing, -80ºC). Collection of blood samples outside of a laboratory setting, however, poses potential problems with respect to proper short-term storage. When conducting research in remote field sites, several hours or even days may pass before samples can be centrifuged and the resultant plasma stored (e.g., -80ºC). Prior to processing, steroids in blood samples may be metabolized (e.g., degraded, converted), leading to erroneous values derived from quantitative analyses such as radioimmunoassays. Alternately, hormones may remain stable under the above-mentioned conditions. There are few published data on the stability of steroids in blood samples collected under field conditions, and no studies are published on reptiles.

Levels of steroids in blood samples may be sensitive to temperature, and this sensitivity may differ among lineages (e.g., mammals versus reptiles). Circulating steroids associated with binding proteins degrade more slowly than free steroids (Pardridge and Mietus 1979), and at high temperatures the rate of steroid dissociation from their binding proteins increases (e.g., Ho et al. 1987). Consequently, metabolism of bound and free steroids may be accelerated at high temperatures. Reptiles have higher circulating concentrations of steroids and binding proteins than mammals, and steroid binding proteins from these two amniote lineages seem to be inherently different both in their specificity and affinity for steroids (e.g., Callard and Callard 1987; Jennings et al. 2000). These facts raise the possibility that blood samples from mammals and reptiles show differences in temperature-sensitive metabolism of steroids.

Research on stability of steroid hormones has been primarily conducted to evaluate the proper storage of mammalian blood and serum in veterinary clinics and hospitals. These results indicate that steroids in plasma and serum are relatively stable when frozen (Bolelli et al. 1995; Kley and Rick 1984; Kley et al. 1985). Refrigeration of plasma samples also yields relatively high stability of steroids (Key et al. 1996; Kley and Rick 1984; Olson et al. 1981; Reimers et al. 1982), although Behrend et al. (1998) reported a significant decline from baseline in cortisol levels in dog serum stored at 4ºC for five days. Storage of plasma at higher temperatures (22–37ºC) often leads to increased steroid hormone metabolism (Behrend et al. 1998; Olson et al. 1981; Reimers et al. 1982, 1983).

It is apparent that the method of choice for storing plasma samples for later hormone analysis is ultra-low freezing (-80ºC), and that storage at higher temperatures for protracted periods can have negative effects on the concentrations of steroid hormones. The conditions to which the samples were exposed in the aforementioned experiments were representative of the various storage methods available in veterinary or clinical laboratories (e.g., ultra-low freezing, refrigeration) rather than the conditions typically encountered in the field, especially in deserts. Because researchers may have no choice but to delay processing blood for 24 h or more, it is critical to determine the effects of sample storage under those temperature and duration conditions.

We were motivated to address the above question for our own studies of seasonal steroid hormone levels of rattlesnakes (*Crotalus* spp.) in the Sonoran Desert (Arizona). Typically, we obtain blood samples and immediately store them in a cooler filled with ice (0ºC), but other times we are forced to carry them on our person (25–40ºC) in the course of sampling animals until we can store them on ice. Centrifugation, collection of plasma, and ultra-low freezing (-80ºC) of these blood samples is done in a laboratory within 6–24 h. In this experiment, we tested whether steroid hormone levels are stable in blood samples from rattlesnakes stored at two temperatures (0°C and 40ºC) for two durations (6 h and 24 h).

Materials and Methods

Subjects.—Twenty (10 male, 10 female) adult Western Diamond-backed Rattlesnakes (*Crotalus atrox*) were used in this study. All subjects were long-term (3–4 years), healthy captives (housed in the Animal Care Facility, Department of Life Sciences, Arizona State University West) that originated from several areas in central Maricopa County, AZ, near the vicinity of Phoenix. Snout–vent length and mass of males (SVL: mean = 89.1 ± SE 2.39 cm, range 74.0–98.0 cm; mass: mean = 480.45 ± 32.81 g, range 278.80–639.3 g, N = 10) and females (SVL: mean = 86.4 ± 1.65 cm, range 78.0–92 cm; mass: mean = 534.65 ± 47 g, range 323.0–773.80 g, N = 10) were similar (SVL: $F_{1,18} = 0.864$, $p = 0.365$; mass: $F_{1,18} = 0.891$, $p = 0.358$). Subjects were housed individually in glass enclosures, and offered laboratory rodents weekly during the active season (March through October). Water was available in glass bowls *ad libitum*. Blood collection occurred on a single day (late morning) in March 2000.

Study design.—Blood harvested from each subject (see below) was partitioned into five treatment groups (split-plot design; Quinn and Keough 2002):

$\mathbf{T_0}$: Blood was immediately centrifuged and plasma stored in an ultra-low freezer (-80ºC). This treatment served as the control.
$\mathbf{T_1}$: Whole blood was placed on ice in a cooler (0ºC) for 6 h, then

centrifuged and stored (-80°C).

T_2: Whole blood was placed in an incubator (40°C) for 6 h, then centrifuged and stored (-80°C).

T_3: Whole blood was placed on ice in a cooler (0°C) for 24 h, then centrifuged and stored (-80°C).

T_4: Whole blood was placed in an incubator (40°C) for 24 h, then centrifuged and stored (-80°C).

Collection of blood and plasma.—Subjects were gently removed from their individual enclosures using hooks and/or tongs, then quickly restrained in a standard squeeze-box. After snakes were secured (1–3 min), 3.0 ml of blood was harvested from their tails (within 1 min) using heparin-treated syringes. All snakes were returned to their enclosures within several minutes of restraint. The blood from each subject was immediately partitioned (0.6 ml) into five 1.5 ml sterile centrifuge tubes, and placed in one of the five treatment groups. Following the respective treatment, blood samples were centrifuged for 4 min at 1200 g, and plasma was collected and placed into 1.5 ml sterile centrifuge tubes and immediately stored at -80°C until radioimmunoassays could be performed (<6 months).

Radioimmunoassay of plasma sex steroids.—Radioimmunoassays (RIAs) of sex steroids examined in this study [testosterone (T) and 17β-estradiol (E2)] were performed on plasma using commercial kits.

RIAs of T followed Schuett et al. (1997), including validation (quantitative recovery and parallelism). Samples in the present study were run in duplicate (N = 200) in two RIAs. The intra-assay coefficients of variation (CV) for T was 9.1% and 11.1%, and the inter-assay CV was 11.9%. The T values are presented as arithmetic means ± SE (ng/ml).

For RIAs of E2, radio-labeled E2, antibody, and a precipitating solution were purchased from Diagnostic Products Corporation (Los Angeles, California; catalog numbers E2D1, E2D2, and N6). Standards were prepared by serial dilutions in methanol of a stock solution. The anti-estradiol antibody was diluted 1:3 in phosphate buffered saline (PBS) containing 1:400 rabbit serum. One hundred microliters of snake plasma (with 300 µl of PBS) was extracted in 5.0 ml of diethyl ether (Fisher Scientific). After removing and saving the diethyl ether layer, the sample was heated to 90°C for 5 min, extracted with an additional 5.0 ml of diethyl ether and 200 µl of PBS. Gelatin (1%) was added to the extract following evaporation of the diethyl ether. Extraction recovery of ^{3}H-estradiol (New England Nuclear, Boston, Massachusetts; NET-381) was 78%. For the RIA, 100 µl of diluted antibody, 100 µl of ^{125}I-E2, and 1.0 ml of precipitating solution were used. A 24 h incubation (4°C) period followed each step. Antibody-bound ^{125}I was separated by centrifugation at 1600 g. Validation involved quantitative recovery and parallelism. Quantitative recovery of E2 added to snake plasma was 100%, and parallelism was demonstrated between the inhibition curve for the standards and dilutions. Samples were run in duplicate (N = 200) in two RIAs. The intra-assay CVs were 7.9% and 12.5%, and the inter-assay CV was 11.9%. The E2 values are presented as arithmetic means ± SE (pg/ml).

Statistical analyses.—Data were subjected to inspection for outliers, normality (skewness and kurtosis), and equality of variance prior to performing statistical tests. Outliers were not detected, and conditions for normality and equality of variance were met. To determine whether or not body size influenced mean hormone levels, we ran simple regressions of body mass versus steroid levels (dependent variable). In those tests we detected a significant relationship between body mass and plasma steroids in males (T: $r^2 = 0.084$, $F_{1,48} = 5.502$, $p = 0.023$; E: $r^2 = 0.241$, $F_{1,48} = 15.218$, $p = 0.0003$); in

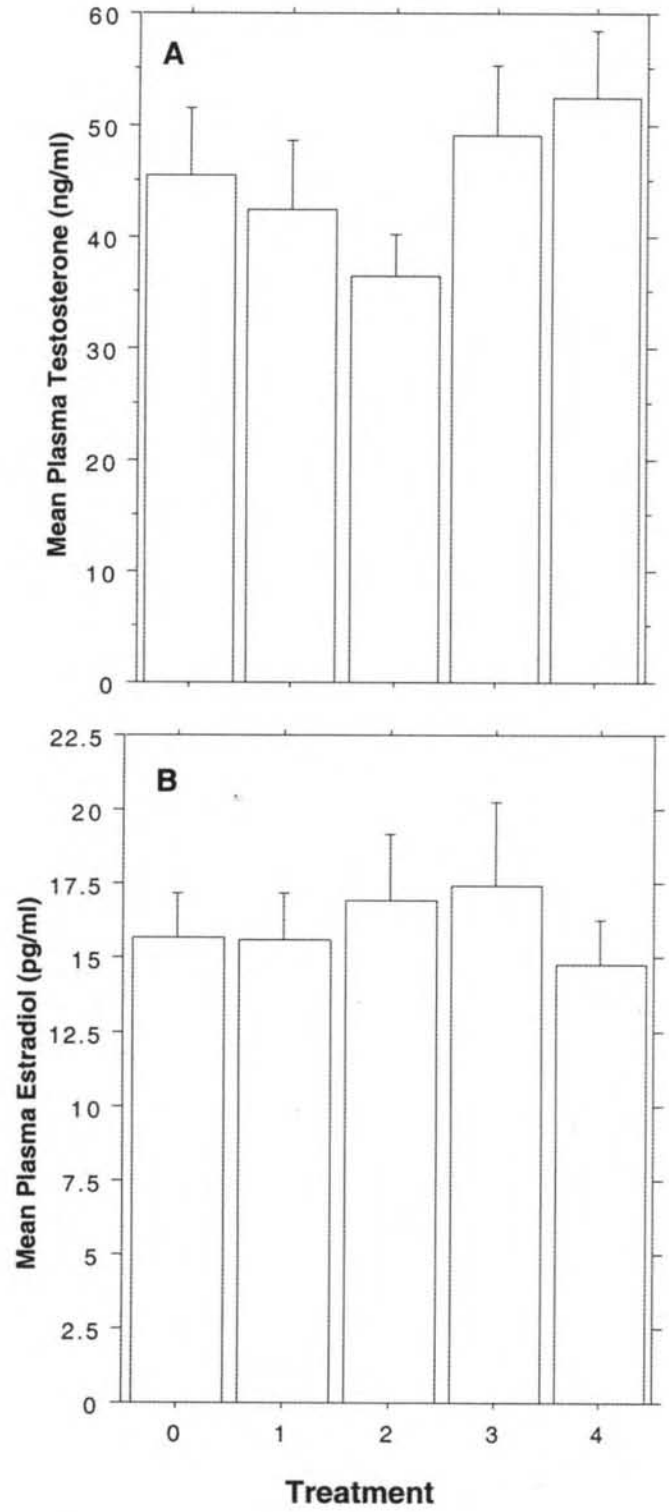

FIG. 1. Mean (± 1 SE) plasma levels of (A) testosterone and (B) 17β-estradiol for adult male *Crotalus atrox* (N = 10) resulting from blood exposed to five treatments (split-plot design). Treatments: 0 = control; 1 = 0°C for 6 h; 2 = 40°C for 6 h; 3 = 0°C for 24 h; and 4 = 40°C for 24 h. See text for details of the statistical analysis.

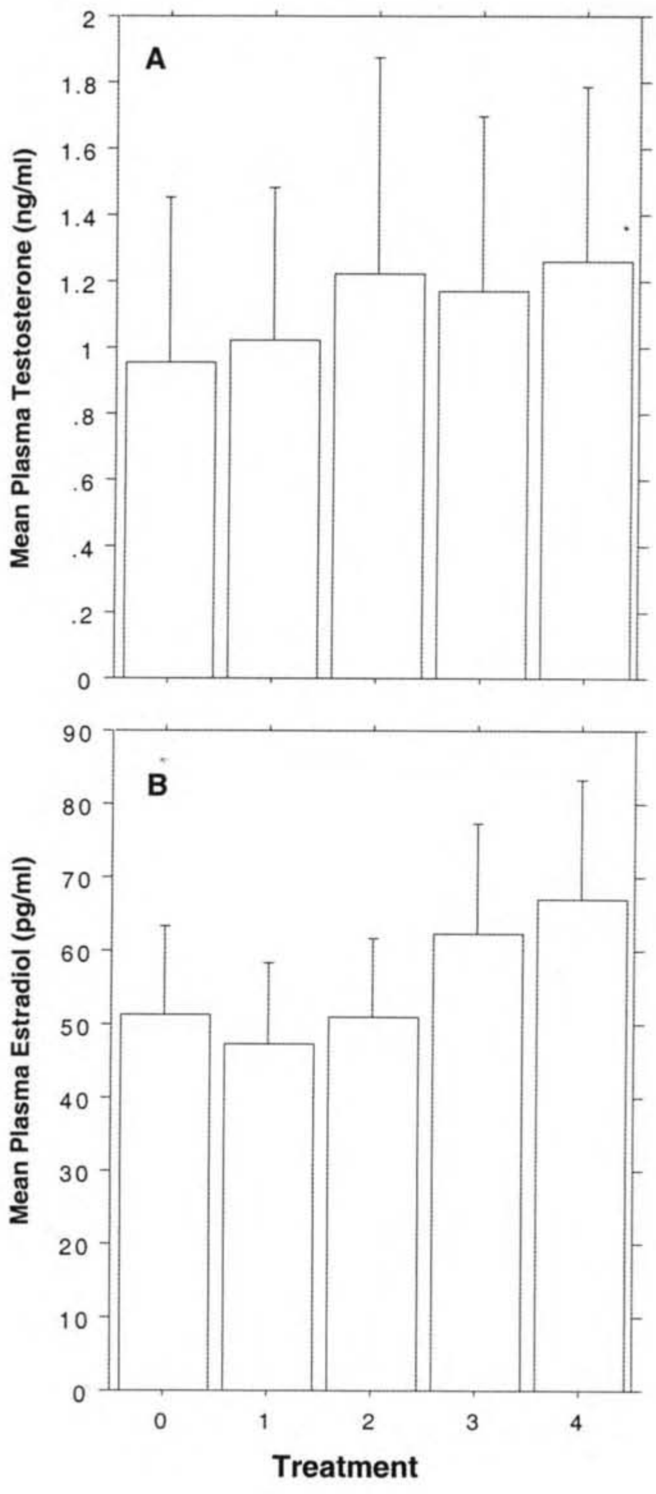

FIG. 2. Mean (± 1 SE) plasma levels of (A) testosterone and (B) 17β-estradiol for adult female *Crotalus atrox* (N = 10) resulting from blood exposed to five treatments (split-plot design). Treatment: 0 = control; 1 = 0°C for 6 h; 2 = 40°C for 6 h; 3 = 0°C for 24 h; and 4 = 40°C for 24 h. See text for details of the statistical analysis.

females, that relationship was significant for T ($r^2 = 0.267$, $F_{1,48} = 17.506$, $p = 0.0001$), but not for E2 ($r^2 = 0.267$, $F_{1,48} = 2.928$, $p = 0.0936$). We thus chose to use body mass as a covariate in subsequent statistical analyses.

Data were analyzed with a three factor split-plot multivariate analysis of covariance without replication, where sex and treatment are crossed fixed factors, subject is a random factor nested within sex, and body mass is the covariate. We achieved an unsaturated model by omitting the test for the treatment*subject (sex) interaction. The α-level of significance was set at 0.05. All tests were performed using SAS (SAS Institute 1999).

RESULTS AND DISCUSSION

We found that steroid hormone levels were significantly different in samples from males and females (sex main effect: $F_{2,63} = 6.03$, $p = 0.004$) (Figs. 1 and 2). There were, however, no differences in hormone levels among treatments (treatment main effect: $F_{8,32} = 0.05$, $p = 0.999$). Also, there was no significant interaction between treatment and sex (treatment*sex effect: $F_{8,128} = 0.74$, $p = 0.659$), indicating that samples from males and females do not respond differently to the treatments.

Our results show that exposure of blood samples from adult male and female *C. atrox* to 0ºC or 40ºC, for two different durations (6 h or 24 h), does not change concentrations of plasma T and E2 (Figs. 1 and 2). Our results agree with the few studies that have investigated the stability of E2 and T in blood and plasma (serum) samples from mammals. Prior to our study, and to the best of our knowledge, the stability of T and E2 in samples from any animal had not been reported at temperatures higher than room temperature (22–25ºC). Because our blood samples can potentially be exposed to temperatures in excess of 30ºC, it was important for us to show that these high temperatures do not lead to steroid hormone degradation/reduction or conversion.

In this study, we tested the effects of storage temperature and duration on the stability of levels of two sex steroids, T and E2, known to be important in the reproductive biology of a range of reptilian species. Although all steroid hormones share a common cholesterol-based backbone and thus may exhibit similar responses to temperature, it is possible that other steroid hormones (e.g., corticosterone, progesterone) could respond differently to storage conditions. There is, moreover, the possibility that desert-adapted reptiles have plasma (and plasma components) that are more durable to conditions of high temperatures for protracted periods. Although we do not have data on other species of reptiles to compare our results, these ideas are important and need to be tested in a range of species, especially in those that are cold-adapted.

In conclusion, we have demonstrated that in Western Diamond-backed Rattlesnakes (*C. atrox*) from Arizona, blood samples exposed to high temperatures for short time periods (≤ 24 h) do not show significant changes in levels of plasma T and E2. Although we recommend that blood samples collected in the field be immediately placed on ice (0ºC) and processed in ≤ 24 h, our data show that negative consequences of short-term storage of blood under the above-discussed conditions are at most minimal.

Acknowledgments.—Numerous people participated in field work, and we are especially appreciative of the help of Laura, Laudon, and Emory Schuett, Matthew Grober, Jack O'Leile, and Ryan Sawby. Edward Van Kirk and William Murdoch, Department of Animal Sciences, University of Wyoming skillfully performed all steroid analyses, and we are grateful for this favor. Dale DeNardo helped in sharpening our focus with respect to experimental design. Ryan Earley assisted with statistical analyses, and we appreciate his help. The manuscript benefited from the comments of two anonymous reviewers. Funding for this research was by a Re-

search Incentive Award, and a Scholarship, Research Creative Activities Award (Arizona State University) to GWS. This research was approved by the IACUC at Arizona State University (98-429R to GWS).

Eleutherodactylus eugeniae was described by Lynch and Duellman (1997) from a small area of cloud forest, at elevations of 1700–2010 m in Provincia Pichincha in northwestern Ecuador. These authors examined very few specimens from the type locality. We collected 29 new individuals (7 juveniles, 9 females, 13 males), 7 from the type locality, and the rest from two new localities (see Appendix I). Herein, we describe aspects of the diet, vocalization, morphological variation, ecology, and reproductive biology of this species.

MATERIALS AND METHODS

Ecological, reproductive, and morphological data were gathered on *Eleutherodactylus eugeniae* from three localities of cloud forests in northwestern Ecuador between 1994 and 2001. This region has an annual precipitation of 2600 mm, with a rainy season from December to May, and moderate rains from July to November; mean annual temperature is 15.6°C (Cañadaz-Cruz 1983). The localities and specimens examined are listed in Appendix I.

We recorded 12 individuals and collected four of them (Appendix I). Calls were recorded from 14–28 February and 10–24 September 1998, and from 27 February–11 March and 13–17 August 1999 in Bosque Integral Otonga reserve (BIO) with a Sony WM D6C Professional Walkman tape recorder and an Optimus Unidirectional Condenser Microphone. Calls were digitized at a sampling rate of 22 kHz at 8-bit precision with the built-in A/D converter on Power Macintosh 7100/80 AV computer and the software Canary 1.1 (Charif et al. 1993). Waveforms and spectra were analyzed with Canary 1.1. Acoustic terminology follows that de-

FIG. 1. *Eleutherodactylus eugeniae*, QCAZ 16041, adult female, SVL 38.4 mm.

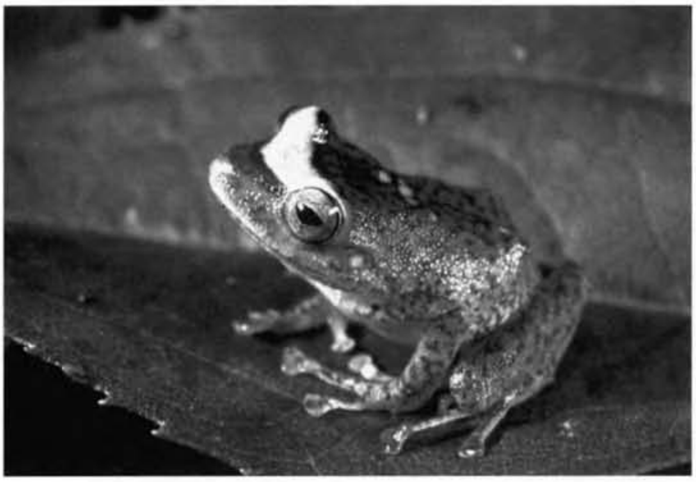

FIG. 2. *Eleutherodactylus eugeniae*, QCAZ 16040, subadult female, SVL 30.3 mm.

scribed in Heyer et al. (1990).

Morphological measurements were taken with digital calipers to the nearest 0.1 mm, and follow the methodology described in Gray and Cannatella (1985) and Lynch and Duellman (1980). Additionally, we measured: internarial distance—distance between nostrils; snout to eye distance—distance from tip of snout to anterior margin of eye; and radio-ulna length—length of flexed forearm from elbow to proximal border of palmar tubercle.

We examined the intestine and stomach contents of 10 females and 10 males (Appendix I). Prey items were identified to the lowest possible taxonomic level. Adults and larvae were analyzed separately because of their differences in body form. The volume of each complete prey item was estimated using the formula for a prolate spheroid (i.e., Volume = $4/3\pi$ [greatest length of prey/2] [greatest width of prey/2]^2; Dunham 1983). The trophic niche breadth, was estimated using the reciprocal of Simpson's (1949) diversity measure

$$(\text{i.e., } B = 1/ \sum_{i=1}^{n} p_i^3).$$

Frog habitat and microhabitat were recorded. Sexual maturity was recognized by the presence of eggs or convoluted oviducts in females and by the presence of vocal slits and enlarged testes in males. Abbreviations as follows: SVL = snout-vent length; IOD = interorbital distance; BIO = Bosque Integral Otonga reserve; REG = Reserva Florística Ecológica Río Guajalito; QZ = Quebrada Zapadores; QCAZ = Museo de Zoología, Pontificia Universidad Católica del Ecuador.

RESULTS

Variation in measurements and proportions are presented in Tables 1 and 2. In addition to the coloration pattern described in Lynch and Duellman (1997) (Fig. 1), a cream-yellow interorbital bar occurs in five individuals (QCAZ 11691, 13119, 13120, 16039, 16040; Fig. 2). Contrary to Lynch and Duellman (1997), we found that the tympanic annulus, described as indistinct externally in males (N = 1), is evident in all the males we sampled (N = 13).

Fifty-nine prey items, corresponding to 18 prey categories, were found (Table 3). The diet of *Eleutherodactylus eugeniae* consisted mainly of insects (86%), followed by spiders (10.2%), and Acari (3.4%). Most of the insects consumed were adult Coleoptera (32%), followed by Araneae (10%), and Hemiptera (8%) (Table 3). Within the identified Coleoptera, the family Chrysomelidae is the most important prey category (Table 3). Volumetrically, the most important items are Coleoptera (adult 26%, larvae 20%) and adult Orthoptera (19%) (Table 3).

In females, the most common prey category is adult Coleoptera (49%), followed by Araneae (14%), and Hemiptera (11%) (Fig. 3); the volume ingested by females consists of adult Coleoptera (32%), Orthoptera (20%), and Dermaptera (14%) (Fig. 3).

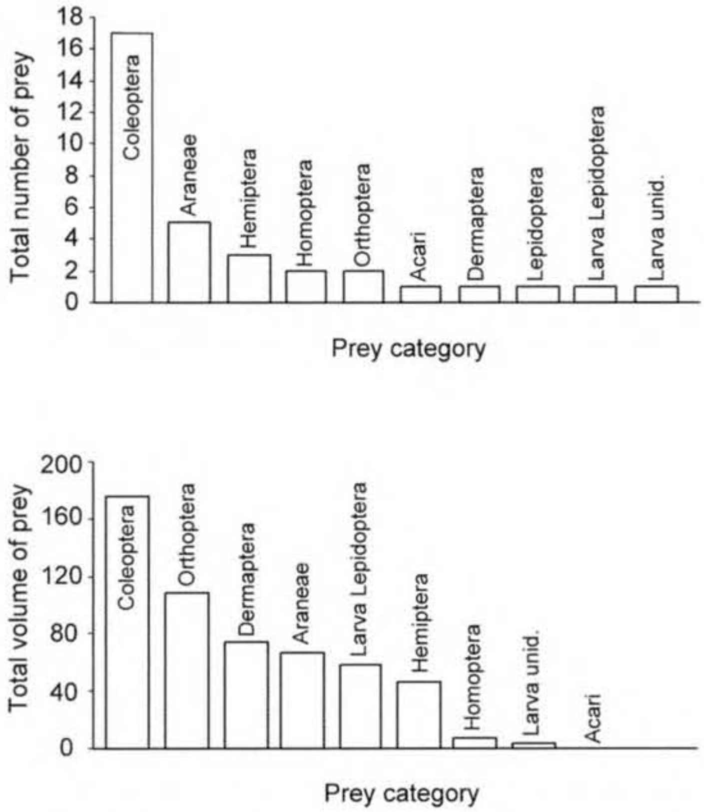

FIG. 3. Numeric (top) and volumetric (bottom) importance of prey categories in females of *Eleutherodactylus eugeniae.*

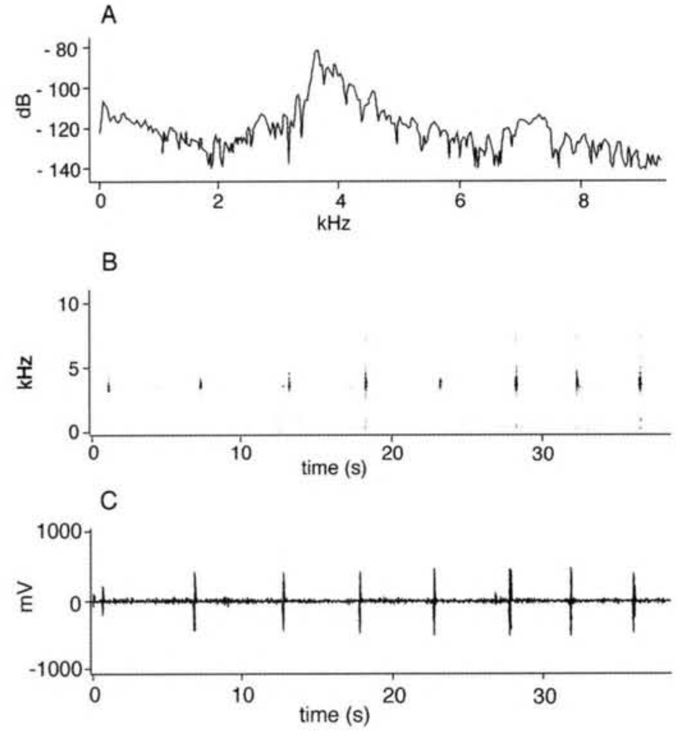

FIG. 4. Call group of *Eleutherodactylus eugeniae*, QCAZ 13199, SVL 27.1 mm. (A) Spectrum, (B) Spectrogram, and (C) Waveform.

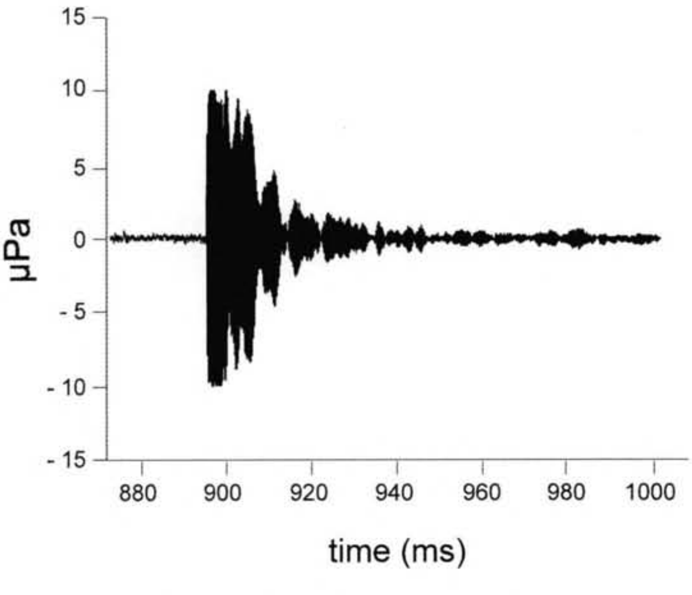

FIG. 5. Expanded waveform of a single call of *Eleutherodactylus eugeniae*, QCAZ 13199, SVL 27.1 mm.

In males, we found only nine prey items (3 Coleoptera, 2 Orthoptera, 1 Acari, 1 Araneae, 1 Hemiptera, 1 Formicidae); this low number prevent us from generalizing about the composition of their diet. On average, we found fewer prey items in males (1.3 prey items per individual) than in females (3.7 items per individual).

We found 66 to 149 ovarian eggs in different developmental stages in six of the eight females examined. They are covered by a membrane pigmented with minute dark brown spots, and have a diameter of 0.1–3.9 mm. Variations in number and size of eggs for

the six females, associated with SVL, locality, and collection date of specimens are summarized in Table 4.

We heard males calling during all of our fieldwork (February and September, 1998; March and August, 1999; June and July, 2001). In *Eleutherodactylus eugeniae,* calls are organized into groups, which are emitted approximately every 15–30 min. Call groups (Fig. 4) are no frequency modulated; they have a duration of 4.7–63.7 s (mean = 32.507 ± 15.547, N = 12), and contain 3–16 calls (mean = 7.694 ± 3.344, N = 12). Each call is formed by one note. Notes have a length of 0.008–0.403 s (mean = 0.131 ± 0.061, N = 12); internote length is 0.473–23.361 s (mean = 5.264 ± 2.578, N = 12); notes are pulsed, with pulses decreasing in amplitude through note (Fig. 5); notes with no noticeable frequency modulation. Fundamental frequency (when evident) is distributed between 99 and 190 Hz (mean = 160 ± 31.224, N = 4) and dominant frequency is between 3370 and 3776 Hz (mean = 3514 ± 117.745, N = 12). The frequency of the first harmonic lies between 6669 and 7415 Hz (mean = 6926 ± 298.771, N = 8) and that of the second harmonic (when evident) between 10257 and 10594 Hz (mean = 10479 ± 119.169, N = 3).

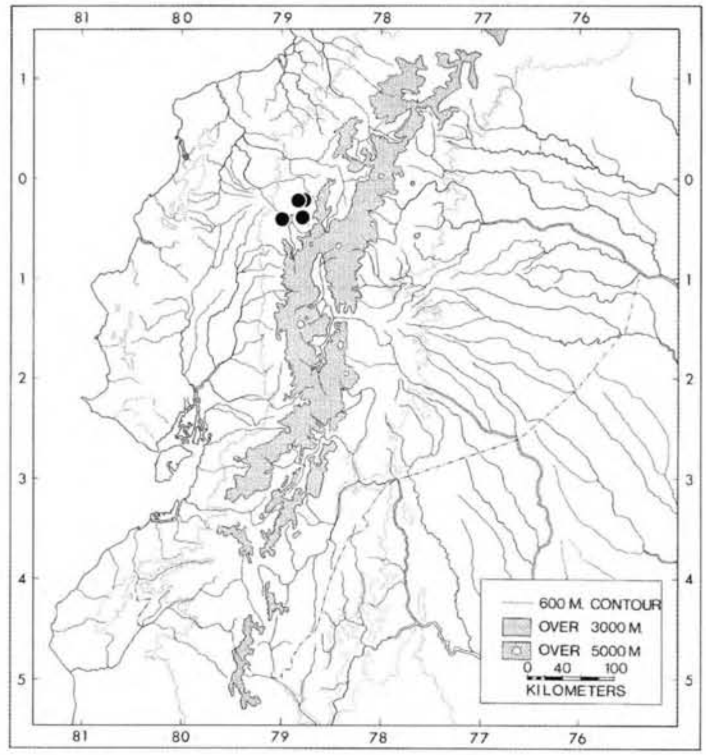

FIG. 6. Distribution of *Eleutherodactylus eugeniae* in Ecuador (circles).

Eleutherodactylus eugeniae was mainly found in disturbed (45.8%, N = 24) and undisturbed primary forests (41.7%, N = 24), but few individuals were found in secondary (8.3%, N = 24) and gallery forests (4.2%, N = 24). Individuals were collected at night, on vegetation between 40 and 340 cm (mean = 180 ± 79.3, N = 26) above ground, but several calls originated near the forest canopy (at least 8 m high). In BIO, we found one individual in a bromelia 50 cm above ground on three consecutive mornings. We also recovered one individual of *Eleutherodactylus eugeniae* (QCAZ 13424) from the bill of a Striped Wood-haunther, *Hyloctistes subulatus* (Aves: Furnariidae), which had been trapped in a mist net placed near its nest.

The known altitudinal distribution and range is here expanded. The species has a known altitudinal distribution of 1700–2200 m and has been recorded from four localities in western Ecuador—viz., QZ, REG, and 6.3 km E Tandapi (ca. 00° 24' S, 78° 47' W) in Provincia Pichincha (Lynch and Duellman 1997); and BIO in Provincia Cotopaxi (Fig. 6).

DISCUSSION

The description of *Eleutherodactylus eugeniae* (Lynch and

TABLE 3. Diet and niche breadth of *Eleutherodactylus eugeniae* based on 20 individuals. No = Total number of prey items found in all individuals examined; No % = Percentage of prey item number in relation to total number of items found in the species; Vol = Total volume of prey category in all individuals examined; Vol % = Percentage of prey item volume in relation to total volume of items found in the species; * = Number of prey items used to calculate volume, this value is used because not all prey were found complete; Frequency = Number of individuals containing prey item.

Duellman 1997) is adequate, but it does not address the range of morphological variation (Table 1; Fig. 2). This information is especially relevant to males, which originally were described on the basis of a single individual.

Eleutherodactylus eugeniae is a nocturnal, sit-and-wait forager; once a prey item is sighted, individuals of *E. eugeniae* have been observed to pursue it for a short distance (< 30 cm) before capture (D. F. Cisneros-Heredia and A. León-Heredia, pers. comm.). Our results (Table 3) agree with the hypothesis that the sit-and-wait foraging strategy might favor capture of relatively large, highly mobile prey (e.g., Coleoptera, Orthoptera, solitary spiders), rather than small prey species with predictable patterns of movement and clumped distributions (e.g. ants, termites, social spiders; Eckhardt 1979; Huey and Pianka 1981; Krebs 1978). Moreover, because *E. eugeniae* principally inhabits the upper strata of the forest, its diet might depend mostly on those arthropods that either fly or climb to the forest canopy; this is supported by the high frequency of Coleoptera, Araneae, and Hemiptera in their stomachs (Table 3). The presence of plant material in the stomachs of eight specimens is considered to be accidental and related to the ingestion of animal prey (Lajmanovich 1995; Zug and Zug 1979).

Males eat fewer prey items than females; this might be a consequence of differences in size (SVL = 30.6–38.6 mm in females; 22.5–28.9 in males), and/or behavior. Several studies have shown a positive relation between the number and size of prey items with the SVL in anurans (Menéndez 2001; Parmelee 1999). Additionally, reproductive effort in calling males might restrict the time spent in feeding activities (Jenssen 1972; Lamb 1984; Woolbright and Stewart 1987). This might be exacerbated in *Eleutherodactylus eugeniae*, in which males seem to call throughout the year. The results of our diet study might be biased toward hard-bodied prey. Specimens collected were not preserved immediately and, surely, many soft-bodied prey were digested (Caldwell 1996; Parmelee 1999). Another variable that probably influenced our results is the spatial and temporal fluctuations of arthropod populations.

Females with eggs larger than 2 mm in April and August (Table 4), and males calling in February, March, June, July, August, and September (Appendix I), suggest that *Eleutherodactylus eugeniae* breeds throughout the year. This mode of reproduction could be sustained by the high humidity of the region and by the reproductive strategy of *Eleutherodactylus:* terrestrial eggs with direct development (Duellman and Trueb 1994; Lynch and Duellman 1997).

The calls of *Eleutherodactylus* are poorly known. The only other call description available for the 61 species of *Eleutherodactylus* that inhabit western Ecuador is of *E. achatinus* in Provincia del Carchi, Ecuador (Lynch and Myers 1983). This lack of information prevents us from comparing the vocalization of *E. eugeniae*

with sympatric or related species.

Our records document the distribution of the species within the Montane Cloud Forest formation as described by Valencia et al. (1999). We collected specimens as high as 340 cm above ground, but most calling individuals were in sub-canopy and canopy. These data suggest, as mentioned by Lynch and Duellman (1997), that *Eleutherodactylus eugeniae* primarily inhabits the upper strata of the forest. Field observations suggest that this species might have site fidelity to diurnal retreats; *E. eugeniae* might depend on trees with epiphytic vegetation (e.g., bromeliads) for diurnal retreats as part of its habitat requirements. The species tolerates habitat disturbance (45.8% of individuals in disturbed primary forest). Individuals have been heard calling in forest patches < 3 m^2 and in solitary trees with bromeliads (D. F. Cisneros-Heredia and A. León-Heredia, pers. comm.), however, it seems to be susceptible to drastic habitat modification (only 8.3% where found in secondary forest, and none in grasslands).

Acknowledgments.—For field assistance we thank M. G. Rivas, C. Tapia, E. Tapia, A. Quiguango, L. A. Coloma, J. F. Freile, J. Chaves, P. Jarrín, and G. Castañeda. We are grateful to D. Paucar and F. Maza for their help in the identifications of some insects. Fieldwork was funded by the Declining Amphibian Populations Task Force (DAPTF) and Fundación Numashir para la Conservación de Ecosistemas Amenazados. We are grateful to G. Onore and Fundación Otonga for the logistic support, and to Idea Wild for the recording equipment. The Ministerio del Ambiente of Ecuador provided collecting permits. For their comments on a previous version of this paper we thank H. Alamillo, P. Burrowes, W. E. Duellman, T. de Vries, E. Greenbaum, R. Joglar, G. Onore, J. Pramuk, S. Ron, and C. Sheil, and especially L. A. Coloma, L. Trueb, W. R. Heyer, and an anonymous reviewer.

Loggerhead turtles, *Caretta caretta*, are highly migratory and use a wide range of broadly separated localities and habitats during their lifetime. In the Pacific, most loggerheads carry out an extensive developmental migration, traveling from nesting areas in Japan and Australia to distant developmental and foraging habitats in the eastern Pacific (Bowen 1995; Bowen et al. 1995; Uchida and Teruya 1988; P. Dutton, unpubl. data). After spending years foraging in the eastern Pacific, these turtles return to their natal nesting beaches for reproduction (Nichols et al. 2000; Resendiz et al. 1998) and remain in the western Pacific for the remainder of their life cycle (Hatase et al. 2002; Kamezaki et al. 1997; Sakamoto et al. 1997). At least some loggerhead turtles, however, apparently do not undertake trans-Pacific migrations and instead remain in the western Pacific for their entire life cycle (Limpus et al. 1994).

Loggerhead sea turtles in the Pacific are adversely impacted by a variety of activities including incidental capture in commercial fisheries, boat strikes, debris ingestion, and intentional harvest (Gardner and Nichols 2001; Suganuma 2002; Wetherall 1996). These have contributed, at least in part, to declines in annual nesting populations in Japan (Suganuma 2002) and Australia (Limpus and Couper 1994; Limpus and Reimer 1994). These reductions have prompted calls for increased research and protection (National Marine Fisheries Service and U.S. Fish and Wildlife Service 1998). However, the development of appropriate management strategies has been hindered by the paucity of data on the biology of loggerhead turtles.

Knowledge of regional size-class distributions of loggerhead turtles can help determine the importance of different marine habitats for various life stages, and provide insights into the geographic variability in life history patterns (Bjorndal et al. 2000; Bolten 2003; Witzell 2002). An important component of this understanding is the size at which juveniles depart the oceanic zone (i.e., seafloor depth > 200 m; Lalli and Parsons 1993) and recruit to neritic foraging habitats (i.e., seafloor depth ≤ 200 m; Lalli and Parsons 1993). Size-at-recruitment to the neritic zone is an important element in the development of sea turtle population models (Bjorndal et al. 2000; Bolten 2003; Crouse et al. 1987) but is poorly understood in the Pacific: current knowledge is based solely on Limpus et al. (1994) who report a neritic recruitment size of 70 cm curved carapace length in Australia based on in-water research. However, the vast size and substantial variation in coastal bathymetry of the Pacific (Briggs 1974) combined with potential life-history differences between Japanese and Australian nesting stocks suggest that the size-at-recruitment for loggerhead sea turtles in Australia might not be representative of the entire Pacific. In the Atlantic, for example, some loggerheads might recruit to neritic habitats at substantially smaller sizes (starting at 25.0 cm curved carapace length along the US Atlantic coast; Musick and Limpus 1997). The purpose of this report is to present information on the size of loggerhead sea turtles in neritic habitats of the Gulf of California. This will provide researchers with a small data set with which to compare demographic data from other locations in the Pacific Ocean.

From 1996 to 2002 we documented the presence of loggerhead turtles at two study areas in the central Gulf of California: Bahía de los Angeles (BLA) and the Infiernillo Channel (CIN), along the coasts of Baja California and Sonora, México, respectively (Fig. 1). These areas are neritic feeding grounds for green turtles, *Chelonia mydas* (Cliffton et al. 1982; Seminoff 2000), and the large abundance of invertebrate fauna (Brusca 1980) suggest they are potential foraging areas for loggerhead turtles. Efforts to document loggerhead turtle presence included: (1) in-water capture of live turtles (2) beach surveys for dead carcasses, and (3) documentation of turtle consumption in human coastal communities.

We attempted to capture loggerhead turtles with entanglement nets (100 m x 8 m, mesh size = 50 cm stretched) placed along the shallow perimeter of each study area. Distance from shore and water depth of netting sites ranged from 50 m to 500 m, and 2 m to 27 m, respectively. Nets were set during both day and night and monitored regularly. Turtles were removed immediately upon capture and held captive up to 24 h. We calculated catch per unit effort (CPUE) with each unit effort equaling the deployment of one 100-m net for 24 h. At BLA and CIN we recorded straight carapace length (SCL; ± 0.1 cm) and curved carapace length (CCL; ± 0.1 cm), respectively, from the nuchal notch to the posterior-most portion of the rear marginals. We converted all CCL measurements to SCL using the conversion equation: CCL = 1.388 + (1.053) SCL (Bjorndal et al. 2000). Prior to release each turtle was double tagged with Inconel tags (Style 681; National Band and Tag Company, Newport, Kentucky); one tag in the first large proximal scale of each front flipper.

To quantify the occurrence of deceased loggerheads we conducted beach surveys along coastal perimeters of each study area. Each survey of the Infiernillo Channel coast covered 16 km of coastline. Surveys were conducted quarterly in March, June, September, and December, 1999–2001 (N = 12). At Bahía de los Angeles each survey encompassed 5 km of shoreline, and surveys were performed monthly from June to September, 1996–2002 (N = 26). In addition, we searched fish camps and refuse dumps near

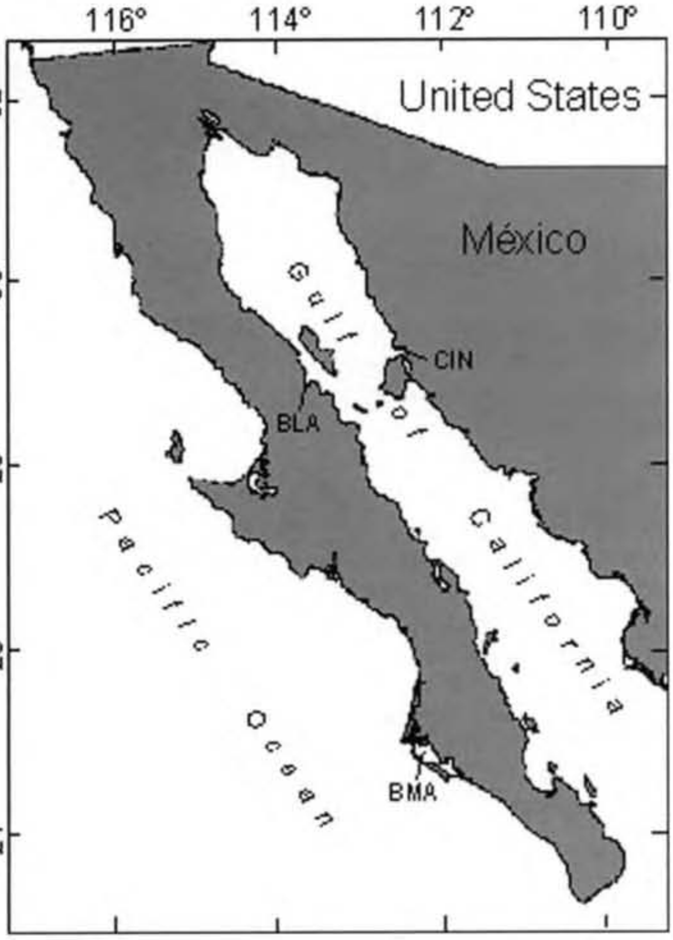

FIG. 1. Map of northwestern México showing Bahía de los Angeles (BLA) and Infiernillo Channel (CIN) regions in the Gulf of California, and Bahía Magdalena (BMA) along the Pacific coast of the Baja California peninsula.

each study site once each year ($N_{BLA} = 7$; $N_{CIN} = 3$). Data were recorded on each sea turtle carcass found, following Gardner and Nichols (2001). Measurements followed the same procedure as that for live-captured turtles. We described presence of external abnormalities, carried out necropsies when possible (Work 2000), and recorded cause of death when known. After each carcass was examined, it was marked with all-weather spray paint or collected to avoid duplicate counting.

We recorded a total of 15 loggerhead turtles during this study: 10 (seven live-captured, two floating dead, and one at a dumpsite) at BLA and five (all at dumpsites) at CIN. Mean straight carapace length of loggerhead turtles was 61.9 (SE = 2.1; range = 43.5–92.7 cm). There was no difference in the mean SCL between the two sites (t = 0.35; $P = 0.73$), nor was there a difference in the mean SCL of live and deceased turtles (t = 0.54; $P = 0.29$). A summary of the size and manner of collection for each turtle is presented in Table 1.

We could not determine the cause of death for the six loggerheads found at dumpsites; however, the fact that all had meat removed and were actively discarded suggests human consumption was likely. For the two loggerhead turtles encountered floating near BLA, mortality might have been from incidental capture in local fisheries: gillnets are commonly utilized in the region for harvest of a variety of finfish species (JAS, pers. obs.). We saw no evidence of contact with oil or tar, no turtles had boat collision or propeller damage, and necropsies of these turtles revealed that both had full stomachs at the time of death.

Overall, the seven live-captured loggerheads from BLA represent 3.2% of all live-captured sea turtles (including *Chelonia mydas*, *Eretmochelys imbricata*, and *Lepidochelys olivacea*) at that area over the same time period (Seminoff 2000). The CPUE for the seven live turtles captured at BLA was 0.014, or one loggerhead capture every 1699 h of netting effort. At CIN, no live loggerhead turtles were captured despite 624 h of netting effort. The eight dead loggerhead turtles represent 6.6% of all deceased turtles found at the two areas (Seminoff 2000; Seminoff, unpubl. data).

We are unaware of the habitats from which deceased turtles originated, but the capture of live turtles provides useful information on the distribution of loggerheads. In the Gulf of California some loggerhead turtles seemingly shift from the oceanic juvenile phase to the neritic juvenile phase at a size that is smaller than that reported for populations in the western Pacific Ocean. While Limpus et al. (1994) report settlement sizes starting at 65.2 cm SCL (70.0 cm CCL) in the southern Great Barrier Reef of Australia, the smallest live loggerhead turtle encountered during this study measured 43.5 cm SCL. Olguin-Mena (1990) and Resendiz et al. (1999) reported minimum sizes of 37 cm SCL and 29.9 cm SCL, respectively, for loggerheads in similar habitats within the Gulf of California. Based on these data, the sizes at which some loggerheads recruit to neritic habitats in the Gulf of California seem more similar to those for loggerheads along the US Atlantic coast (25-46 cm CCL; Bjorndal et al. 2001; Musick and Limpus 1997).

Although the mechanisms of dispersal into the Gulf of California are unclear, our study illustrates the potential variability of loggerhead life-history in the Pacific Ocean. The factors that contribute to apparent differences in neritic recruitment size are poorly understood and caution should be exercised in formulating theo-

TABLE 1. Summary of *Caretta caretta* recorded from the Gulf of California 1996 to 2002. Disposition codes include: L – live captured; F – floating in water; D – found dead at dumpsite.

Date	Size (cm SCL)	Disposition
	Bahía de los Angeles	
1 January 1996	47.7	F
4 September 1997	69.4	L

[c] Data from Ramirez Cruz et al. (1991). Data are for live-captured turtles.

ries about neritic recruitment patterns based on the few studies that have occurred to date. Moreover, as reported for Atlantic loggerheads by Witzell (2002), the shift from pelagic to coastal habitats might be flexible. Some immature turtles might remain in the pelagic habitat longer than hypothesized, and some might move back and forth between pelagic and coastal foraging habitats. These variable data underscore the need for additional comparative studies of intrinsic and environmental effects on loggerhead turtles to assess their relative influence on habitat preference.

Considering that most sea turtles attain maturity at or near mean nesting size (Chaloupka and Musick 1997), the size range in this study (43.5–92.7 cm SCL) is indicative of a population consisting primarily of juveniles and sub-adults. All but one turtle encountered during this study was smaller than the mean nesting size in Japan (89.0 cm SCL; Uchida and Nishiwaki 1982). A preponderance of juvenile sizes has also been reported for loggerheads along the Pacific Coast of Baja California (Nichols 2003; Olguin-Mena 1990; Ramirez Cruz et al. 1991). These findings are consistent with the prevailing life-history model that depicts the eastern Pacific as an important juvenile developmental habitat (Bowen et al. 1995).

The mean size of loggerheads examined in this study (61.9 ± 2.1 cm SCL) is significantly larger than that reported by Ramirez Cruz et al. (1991) for live loggerheads from the Pacific coast of the Baja California Peninsula ($t = 6.029$, $P < 0.0001$; Table 2; Fig. 1). Moreover, the maximum SCL in this study (92.7 cm) is larger than that reported for both live (58 cm; Ramirez Cruz et al. 1991) and stranded (83.4 cm; Gardner and Nichols 2001) loggerhead turtles from the Pacific. Consistent with our results, Márquez (1969) reported that the larger of two loggerheads found in the Gulf measured 92.0 cm SCL. Although the greater size of loggerheads in the Gulf of California relative to the Pacific coast of the Baja California peninsula might be because of small sample sizes, we believe this difference might result from the semi-enclosed nature of the Gulf of California. Perhaps the Baja California peninsula acts as a land barrier, delaying the westward journey of loggerheads in the Gulf of California. Nichols et al. (2000) reported that a loggerhead turtle returning to Japan from Baja California maintained a westward bearing regardless of surface current patterns. If bearing-specific homing is characteristic of all Pacific loggerheads, then return movements of individuals in the Gulf of California, that must first move south to depart the Gulf, might be delayed relative to those of loggerheads on the west side of the Baja California peninsula that have an unimpeded westbound route. We encourage additional studies to substantiate the comparatively large mean size observed in this study. Moreover, satellite telemetry might be a useful tool to investigate this 'peninsular barrier' hypothesis and establish the route taken by loggerheads as they depart the Gulf of California.

The low capture per unit effort in this study suggests that the Gulf of California might not provide critical habitat for loggerhead turtles in the eastern Pacific. Nevertheless, given consideration of the recent population decline for Pacific loggerheads, the Gulf region should be included as a target area for efforts to protect this endangered marine species.

Acknowledgments.—This research was supported by Wallace Research Foundation, Earthwatch Institute, and David and Lucile Packard Foundation. We are indebted to J. Gilmore, G. Hoeffer, J. Lopez, L. Monti, G. Nabhan, B. Resendiz, H. Romero, O. Savin, T. Smith, L. Yarnell, and the Earthwatch Team Members for assistance with field activities. We thank A. Bass, A. Bolten, K. Lohmann, Y. Matsuzawa, and W. Witzell for helpful comments that improved previous versions of this manuscript. Turtle capture was authorized by Secretaria del Medio Ambiente, Recursos Naturales, y Pesca, México (Permit Nos. 150496-213-03, 280597-213-03, 190698-213-03, and 280499-213-03). All turtle handling was in full compliance with University of Florida IACUC protocol (#Z049).

The Gender of the Genus *Scinax* Wagler, 1830 (Anura, Hylidae)

ULISSES CARAMASCHI

Quinta da Boa Vista, 20940-040 Rio de Janeiro, RJ, Brazil
e-mail: ulisses@acd.ufrj.br

Johann Georg Wagler (1800–1832), German naturalist with a special interest in herpetology and ornithology, produced major treatises in his short life (Adler 1989). Among them, his "Natürliches System der Amphibien" (1830) is a comprehensive classification, in which the first 129 pages were dedicated to mammals and birds, and the remainder to the "Amphibia" (reptiles included). Higher taxa (order, family, genus) were diagnosed, species were listed with synonymies (some also diagnosed), and footnotes with comments on identification and etymology of the names are provided (Vanzolini 1977).

In this work, Wagler proposed the generic name "*Scinax*, Schnellfrosch" (= "*Scinax*, quick frog") with the following diagnosis, freely translated from Latin: "Similar to preceding [*Phyllomedusa*]; body somewhat long; head narrow and snout somewhat long; fingers slender, cylindrical, ending in globulous disc, without webbing; foot half webbed, except the free first toe. (Throat in not inflatable vesicle.) America." The species included in the new genus were *Hyla aurata* Wied-Neuwied, *Hyla variolosa* Spix, and *Hyla bipunctata* Spix. *Hyla variolosa*, currently a junior synonym of *Hyla punctata* (Schneider), was also placed as a species belonging to the genus *Auletris* Wagler. In a footnote, the

etymology is quoted as "Scinax agilis ad subsiliendum" (= *Scinax* agile to leap).

Wagler provided no evidence on the gender of the name *Scinax* and did not combine his genus with any of the included species, which appeared as feminine names associated with the feminine genus *Hyla*. The same is observed for the currently masculine genera *Dendrobates* (included *Hyla nigerrima* Spix, *Hyla tinctoria* Daudin, and *Hyla trivittata* Spix), *Phyllodytes* (included *Hyla luteola* Wied-Neuwied), and *Hemiphractus* (included *Rana scutata* Spix), for example.

The first combination of a species name with *Scinax* appears in Tschudi (1838), in the list of synonyms of *Hypsiboas luteola*, as "*Scinax aurata, variolosa, bipunctata* Wagl." The gender adopted was intentionally feminine whereas in the same list the combination "*Auletris variolosus* Wagl." is also present, denoting clear utilization of *Auletris* in masculine gender, although it had been treated in the same inexplicit way by Wagler (1830) as he did for *Scinax*. Fitzinger (1843) confused the situation by including *Scinax* Wagler as a synonym of *Hypsiboas* Wagler, with *Hyla punctata* Daudin as its type species ("typus"). This designation is invalid according to the International Code of Zoological Nomenclature (ICZN 1961, 1964, 1985, 1999), because *Hyla punctata* was not originally included in the genus *Scinax*.

Günther (1858) placed *Scinax* (and *Calamites*, *Hypsiboas*, *Auletris*, *Hyas*, and *Phyllodytes* Wagler) in the synonymy of *Hyla* Laurenti, 1768, and this arrangement was followed by subsequent authors (e.g., Boulenger 1882; Nieden 1923), or only *Phyllodytes* was excluded as a valid genus (e.g., Bokermann 1966; Gorham 1974; Duellman 1977; Frost 1985, 2002).

Reviewing Spix's specimens of anurans housed in the Royal Cabinet of Natural History in München, Peters (1872) used the combination *Scinax bipunctata* Wagler, 1830 as a synonym of *Hyla bipunctata* Spix, 1824. He did not discuss that combination nor present any reason to consider *Scinax* feminine. Apparently, he simply followed the combination derivative of Wagler (1830).

Stejneger (1907), by subsequent designation, defined *Hyla aurata* Wied-Neuwied as the type species for *Scinax* Wagler. Although Stejneger's studies were characterized by a critical, scholarly approach, with detailed descriptions of identifiable specimens and careful designations of type species and type localities (Adler 1989), he did not express clearly the new combination nor his opinion on the gender of *Scinax*.

The *Hyla rubra* group was defined by León (1969) to accommodate a set of species occurring in Mexico and Central America; this group was recognized by Cochran and Goin (1970) and Duellman (1970). Several phenetic subgroups were proposed subsequently for the *H. rubra* group by Duellman (1972) and Lutz (1973).

The genus *Ololygon* Fitzinger, 1843 (type species, by monotypy, *Hyla strigilata* Spix, 1824) was resurrected by Fouquette and Delahoussaye (1977) to accommodate the species formerly included in the *Hyla rubra* group (*sensu lato*). *Ololygon* is neutral in gender (*cf.* ICZN 1964, 1965), but the authors made no attempt to combine grammatically the several names of species to the genus, treating them irrespectively as feminine, directly transposed from *Hyla*. They included 48 species in five species groups of *Ololygon* and referred ten other species to the genus. The generic arrangement of Fouquette and Delahoussaye (1977) was disputed explicitly or implicitly by employing *Hyla* instead of *Ololygon* (see references in Faivovich 2002) or adopted (e.g., Caramaschi and Kisteumacher 1979; Hoogmoed and Gorzula 1979; Harding 1983; Frost 1985; Duellman 1986; Peixoto 1987, 1988a,b; Peixoto and Weigoldt 1987; De la Riva 1990; Heyer et al. 1990; Henle 1991).

Pombal and Gordo (1991) noted that *Scinax* Wagler, 1830 has priority over *Ololygon* Fitzinger, 1843, but they did not make taxonomic changes and conservatively adopted the genus *Hyla* to accommodate two new species that currently are associated with *Scinax* (*S. jureia* and *S. littoralis*).

Duellman and Wiens (1992) followed Pombal and Gordo (1991) in recognizing the seniority of *Scinax* over *Ololygon*. These authors presented a comprehensive approach to the problem, by resurrecting and diagnosing the genus *Scinax* and discussing the nomenclature relevant to the genus, by designating and describing a neotype (KU 125383) for *Hyla aurata*, the type species of that genus, and thereby placing its type locality to Maracás (13°27'S, 40°26'W), State of Bahia, Brazil. They also hypothesized intra- and intergeneric relationships and tentatively updated the species composition of the genus. These authors considered the generic name *Scinax*, from the Greek "*skinos*" meaning quick or nimble, an appropriate name for these agile frogs, and clearly stated that the gender is feminine.

Köhler and Böhme (1996) argued that there is no Greek word "skinos," as presented by Duellman and Wiens (1992), and that the proper etymology given by Wagler (1830) was "***Skinax*** *agilis ad subsiliendum*." Quoting a bio-etymological dictionary, they stated that "scinac - Gr. *skinax*, genit. *skinakos*, quick, nimble. Ex.: *Scinaco-pus* (Ins.), *Scinax* (Rept.)" Moreover, they affirmed that the Greek word *skinax* has been rarely used in the classic literature; they cited the hellenistic poet "***Nikander*** (200 b.Ch.) used it as an attribute for the hare (Gr. - lagos)." Besides they considered that the linguistic derivation is not clear, but most likely derived from "*kindax*" resp. "*kinein* - G. to move", they stated that, in any case, its gender is clearly masculine. So, according to Article 11g of the International Code of Zoological Nomenclature (ICZN 1985), they concluded that "*Scinax* has therefore to be treated as a noun of masculine gender." Following this conclusion, Köhler and Böhme (1996) cited 29 species names as masculine, following the valid species names associated previously with the genus *Scinax* as feminine by Duellman and Wiens (1992, 1996). The masculine gender was adopted by Kwet and Di-Bernardo (1999), Izecksohn and Carvalho-e-Silva (2001), and Lescure and Marty (2001) in studying regional anuran faunas, by Peixoto (2002) in describing a new species (*Scinax arduous*) and treating all species referred and included in the *Scinax perpusillus* species group by him, and by Alves and Carvalho-e-Silva (2002) in describing the tadpoles of *S. alter* and *S. cuspidatus*.

According to Gow and Scholfield (1953), Nikandros of Kolophon (ca. 140 BC) was a Greek priest of Apollo, didatic poet, grammatist, and chronicler, author of the "Theriaka" and of the "Alexipharmaka," currently known only by fragments, and of a "Georgica," lost but later imitated by Virgil. The reference to the hare is in the "Theriaka" but there is no evidence that he utilized "*skinax*" as a masculine or a feminine adjective. It is noteworthy that Wagler selected such a rare word for the generic name.

Reactions to the proposition of Köhler and Böhme (1996) appeared early in 2000. Guix et al. (2000), in a nomenclatural note,

mentioned that they opted for the feminine gender of *Scinax* because this word comes from the Greek "skinax" (= agile), which can be utilized as masculine or as feminine, and that Wagler (1830) originally combined *Scinax* to three species in feminine gender. Therefore, according to the Article 30.1.4.2 of the International Code of Zoological Nomenclature (ICZN 1999), they concluded that this gender must prevail (but, they stated, see also Köhler and Böhme 1996). The nomenclatural position of Guix et al. (2000) was followed by Langone (2001) and Faivovich (2002) without additional comments.

Duellman (2001) discussed the etymology and the gender of *Scinax*, referring that Duellman and Wiens (1992) considered that the generic name is feminine, and that Köhler and Böhme (1996) incorrectly argued for a different interpretation with the gender being masculine. To corroborate that proposition, Duellman (2001) cited the Fourth Edition of the International Code of Zoological Nomenclature (ICZN 1999; Article 30.1.4.2), which clearly states: "A genus-group name that is or ends in a word of common or variable gender (masculine or feminine) is to be treated as masculine unless its author, when establishing the name, stated that it is feminine or treated it as feminine with an adjectival species-group name." Arguing that Wagler (1830), when proposing the generic name *Scinax*, treated it as feminine by using its combination with three feminine specific names (*aurata*, *bipunctata*, and *variolosa*), Duellman (2001) concluded that the suggestion of Köhler and Böhme (1996) that specific names of *Scinax* should have *-us* endings must be disregarded. In fact, Duellman (2001) should have referred to the 1985 edition of the Code because this was in effect when Köhler and Böhme (1996) proposed their ideas. Fortunately, there is no difference in Article 30.a.i contained in the 1985 and 1999 editions of the Code, and thus no change is required of Duellman's proposition.

Cannatella (in Frost 2000) stated that *Scinax* is a third declension noun, and those ending in *-x* are usually feminine, although there are several exceptions. This is true for names ending in *-nx* (-gx, in Greek) and *-ix* (-ix, in Greek), which are feminine, but not for *-ax* (-ax, in Greek), which is masculine (see Appendix D in the editions 1961 to 1985 of the Code). Again according to Cannatella, "the etymology provided in the original coining of the name ('*agilis ad subsiliendum*') is of no help. *Agilis* is a two-ending adjective and so could be masculine or feminine. *Ad subsiliendum*, despite the neuter implication of the *-um* ending, is a gerund expression in the accusitive case (usually used with *ad* in this form), denoting a sense of purpose. 'Agile or light for the purpose of leaping' would be a translation. But this modifying phrase provides no clue about gender, other than it is not neuter." In fact, in Greek, according to the meaning, most words designating actions are feminine (Papavero 1994), but this also does not clarify unequivocally the gender of *Scinax*.

Frost (2000) considered that the argument for masculine gender is weak as is the argument for feminine gender. Therefore, he assumed "*Scinax* to be a common gender and have taken the first combination of *Scinax* as analogous to the first revisor action in setting gender, which is, in this case, feminine, based on the first use in combination by Peters, 1872 (*Scinax bipunctata*, now in *Hyla*), which has also been the predominant usage." He apparently overlooked that the first usage of the combination of *Scinax* with a specific name was by Tschudi (1838), as feminine (see above); thus, Peters (1872) cannot be accepted as analogous to a first revisor action. In fact, if applicable, the work of Duellman and Wiens (1992) is a real first revision of the genus *Scinax*, and there its gender is also feminine.

Kwet (2001) presented a brief history of the problem and agreed with Köhler and Böhme (1996) by concluding that *Scinax* is a name of variable gender. Consequently, according to Article 30.1.4.2 of the current Code (ICZN 1999), which states that "a genus-group name that is or ends in a word of common variable gender (masculine or feminine) is to be treated as masculine unless its author, when establishing the name, stated that it is feminine or treated it as feminine in combination with an adjectival species-group name," Kwet (2001) determined that *Scinax* is masculine. On the other hand, respecting the application of the Article 24.2 (ICZN 1999), which rules the Principle of the First Reviser, Kwet (2001) correctly argued that it does not concern the determination of gender of names and rejected Frost's (2000) proposition. Finally, arguing that *Scinax* was not in use over more than a hundred years until its revalidation by Duellman and Wiens (1992) and, after that, both masculine and feminine spellings of *Scinax* were widely used in current literature, without a clear predominance of one or another, the masculine gender should have priority.

Savage (2002) argued that the Greek word *skinax* (plural *skinakos*) would actually be an adjective used to modify both masculine and feminine nouns with no change in termination. In the case of the generic name, *scinax* would be an adjective used as a noun ("the nimble one"), and contrary to Köhler and Böhme (1996) would not be "clearly" of masculine gender. By citing the Article 30.1.4.2 of the current Code (ICZN 1999), which stated that when a generic name is based on a word of variable gender and was not clearly indicated as feminine by the author establishing the name, it is to be treated as masculine, notwithstanding the reference of Peters (1872) to *Scinax bipunctata*, he concluded that *Scinax* must be regarded as of masculine gender.

Noting that the gender of *Scinax* is controversial, but resolved arbitrarily by Article 30.1.4.2 of the Code (ICZN, 1999) and that Köhler and Böhme (1996) suggested that the gender of the name *Scinax* is masculine, Frost (2002) reinstated the observations of D. Cannatella presented in Frost (2000) and that the first action applying a specific gender to *Scinax* was that of Peters (1872), who treated it as feminine (as *Scinax bipunctata*, now in *Hyla*). He considered this first action in keeping with at least one interpretation of the gender of *Scinax* and that it has been the predominant usage subsequently. Nonetheless, as Frost (2002) noted, contrary to this purportedly predominant usage, the Code (ICZN 1999) does set the gender of *Scinax* to be masculine; Kwet (2001) is referred to as discussing the gender and the Code. Thus, Frost (2002) recognized 84 valid species names for *Scinax*, combining them as masculine when appropriate.

In conclusion, by considering: (1) that Wagler (1830) did not use *Scinax* in combination and therefore did not demonstrate the intended gender of his genus; (2) that Greek words ending in *-ax* are normally masculine and according to its meaning part of the words designating actions, as is *Scinax*, are masculine; (3) that the Principle of the First Reviser does not apply to determination of gender of names; (4) that there is no clear predominance of masculine or feminine usage for *Scinax* in the current literature; (5)

that the Code (ICZN 1999) clearly states that a name of common variable gender is to be treated as masculine; and (6) that in the checklist of amphibian species by Frost (2002) the gender is now consistently used as masculine, I hereby reassert that the gender of the genus *Scinax* should be considered masculine.

Currently the genus *Scinax* is composed by 84 species, as recognized by Frost (2002), plus *Scinax arduous* Peixoto, 2002. However, a number of species currently placed in *Hyla* probably belong in the genus *Scinax* (Frost 2002), several nominal species currently in the synonymy of other species are actually valid species, and a number of new species are waiting description.

Acknowledgments.—I thank D. M. Teixeira for the help with the classic work of Nikandros of Kolophon; A Kwet for sharing his findings on the gender of *Scinax* with me; C. A. G. Cruz, D. R. Frost, C. F. B. Haddad, W. R. Heyer, O. L. Peixoto, and J. P. Pombal, Jr. for comments on the manuscript; and the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) for the research fellowship.

Literature Citations for Slider Turtle (*Trachemys scripta*) Requested

Carl Ernst and Michael Seidel are preparing the species account (Catalogue of American Amphibians and Reptiles) for *Trachemys scripta*. In an effort to be thorough and because the literature on this turtle is so voluminous, they are seeking the assistance of anyone (author, bibliophile, reader) who is aware of publications on this species which might be overlooked by a routine search of the literature. References to publications in non-U.S. or technical journals would be especially helpful. Citations can be forwarded to: *Michael E. Seidel, Department of Biological Sciences, Marshall University, 400 Hal Greer Boulevard, Huntington, West Virginia 25755-2510, USA; tel. Krefft's River Turtles, *Emydura krefftii*, inhabit many of the rivers and streams along the eastern Queensland coast (Cogger 2000), yet its ecology in the wild is poorly understood, particularly within tropical populations (Cann 1998). Previous studies on *E. krefftii* (Georges 1982a, b; Georges 1983) were conducted on Fraser Island, Southeast Queensland. However, the Fraser Island population might be genetically distinct from the mainland populations and might be an undescribed species (Cann 1998). There are no studies on the ecology of *E. krefftii* from mainland populations (Cann 1998).

Many freshwater turtles, including *Emydura* spp. exhibit sexual size dimorphism, with females being larger than males (Cann 1998; Chessman 1978; Georges 1982a; Spencer 2000). Larger female body size might be the result of selection for increased fecundity (Ernst et al 1994; Gibbons and Lovich 1990; Viosca 1933). In addition, females of a number of species including *E. krefftii* have relatively larger heads than males, with both sexes undergoing macrocephaly with increasing age (Cann 1998). Greater head size in females might function to increase the size range of food items, perhaps in response to calcium depletion after oviposition (Cann 1998; Chessman 1978).

This study describes sexual dimorphism in a population of *E. krefftii* from Ross River. The Ross River is located in the seasonal wet-dry tropics of North Queensland, Australia. The study site was a 360 m portion of the Ross River, downstream of the Aplins Weir, (19°15'59"S, 146°45'6"E) at Douglas, Townsville. Sampling was carried out between the 13 August and 10 October 2001 in the late dry season when river flow and water levels are lowest. Turtles were trapped using modified crab pots (8 x 8 cm mesh) baited with chicken carcasses, following the hoop trap design of Legler (1960). In addition, a few turtles were collected with dip nets. There were 22 days in which traps were set. Each day, four traps were set for a three-hour period and checked hourly.

From each individual, shell dimensions were measured to the nearest mm with a flexible tape. Mass was recorded to the nearest 20 g using Elson spring balance scales with 1000 g or 5000 g capacity. Carapace length was measured as curved carapace length along the midline and carapace width was measured as the curved horizontal distance across the highest point of the carapace. Plastron length was measured as the curved distance along the ventral midline, and plastron width was measured across the proximal end of the femoral plates. Cranial measurements were made to the

nearest mm using Unimax dial calipers. Cranial length was measured, from the snout tip to the posterior edge of the quadrate bones. Cranial width was measured at the widest point, across the tympanic membranes.

Turtles were sexed based on the marked sexual dimorphism in tail morphology. Male *E. krefftii* have considerably broader and longer tails than females (Cann 1998). Each turtle was given a unique mark (Cagle 1939) and released at the original site of capture.

Data were log-transformed prior to analysis so as to meet assumptions of normality and homogeneity of variance. Intersexual comparisons of mass were made using univariate ANOVA. In order to describe differences in body shape, or relative morphology, the effects of body size were removed using standardized residuals calculated from regressions of each morphological character against body mass. These measures of relative morphology were then compared between sexes, using univariate ANOVA.

A total of 126 *Emydura krefftii* were marked (72 females and 54 males). Mass frequency distributions seemed to be normally distributed in both males and females (Fig. 1). The greater frequency of females, compared to males, in the larger size classes is clearly evident. Mean body mass was significantly greater in females than in males ($F = 17.25$, $P < 0.001$, Table 1). Additionally, mean carapace length and width, plastron length and width, and head length and width were also greater in females (Table 1).

Significant linear relationships, on a log-log scale, were evident between body mass and all other measurements (Fig. 2). The slope of each of these relationships approximated isometry (slope = 0.33), indicating generally proportionate growth over most of the size range. However with differences in body mass removed, females still had significantly larger cranial length, cranial width, and carapace width (Table 2).

Female *E. krefftii* are significantly larger than males. In addition, with the effects of body size removed, female *E. krefftii* have relatively greater carapace widths than males. These results are consistent with those from other genera of freshwater turtles from around the world, with sexes usually significantly differing in aspects of their morphology (Aresco and Dobie 2000; Cann 1998; Chessman 1978; Ernst et al 1994; Gibbons and Lovich 1990;

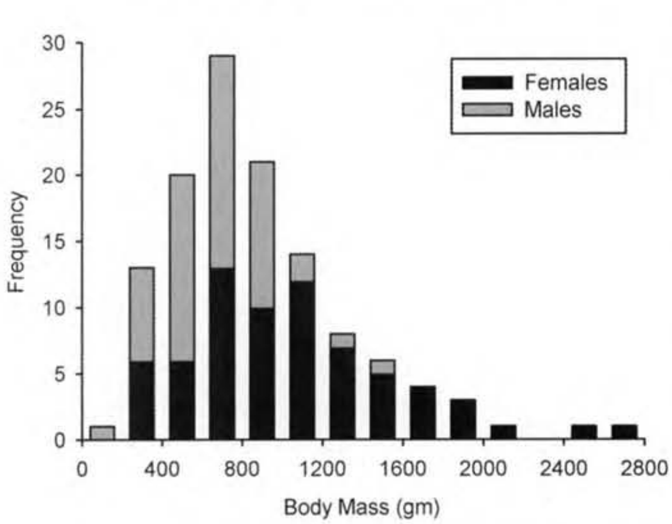

FIG. 1. Frequency distribution of body mass for male and female *Emydura krefftii* (N = 126).

TABLE 1. Mean ± SE of eight morphological parameters for male and female *Emydura krefftii*.

Parameter	Male	Female
Carapace Length (mm)	183.5 ± 3.95	208.9 ± 4.26
Carapace Width (mm)	148.1 ± 2.90	173.3 ± 3.70
Plastron Length (mm)	143.7 ± 3.05	164.5 ± 3.33
Plastron Width (mm)	56.9 ± 1.25	66.6 ± 1.49
Cranial Length (mm)	33.9 ± 0.64	39.4 ± 0.86
Cranial Width (mm)	27.8 ± 0.50	33.4 ± 0.84
Body Mass (grams)	650 ± 37.8	1010 ± 61.7

TABLE 2. ANOVA results for six relative morphological parameters with the effects of mass differences removed (calculated utilizing residuals) comparing male and female *Emydura krefftii*.

Parameter	F (d.f = 1,120)	Significance
Relative Carapace Length	0.368	0.545
Relative Carapace Width	9.910	0.002
Relative Plastron Length	0.280	0.598
Relative Plastron Width	3.066	0.083
Relative Cranial Length	4.670	0.033
Relative Cranial Width	11.428	0.001

Viosca 1933). Sexual dimorphism in turtles often has been attributed to differences in reproductive strategies (Gibbons and Lovich 1990). Greater mass, and relative width, might increase fecundity in female *E. krefftii* because they can accommodate more eggs. In contrast, larger body sizes (and the associated energetic and resource costs) are generally regarded as not advantageous for males in terms of reproductive success.

In addition to attaining greater overall body size, female *E. krefftii* also had larger heads than males. The muscular and bony development associated with greater cranial size is likely to have important functional and ecological consequences. In particular, greater head size might increase niche breadth in female *E. krefftii*. However, dietary studies in the genus *Emydura* do not support a niche breadth hypothesis. Studies of *E. macquarii* have found little difference between the diets of males and females (Chessman 1978). These turtles were omnivorous, but the majority of their diet consisted of terrestrial and aquatic plants (Chessman 1986). Similarly, Georges (1982b) found no difference in diet between sexes in *E. krefftii* on Fraser Island. These turtles were utilizing aquatic insects, with an ontogenic shift to larger insects and crustaceans.

We have described marked patterns of morphological variation between sexes in *E. krefftii*. Further work is required to examine the functional and ecological implications of this variation. In particular, dietary differences between sexes, as well as ontogenic shifts in dietary habits of *E. krefftii* need to be explored. Additionally, the hypothesis that reproductive success is related to body size in female *E. krefftii* remains to be examined.

Acknowledgments.—Sincere thanks to Diane Barton and Simon Fearn for much logistic support, and to the Queensland National Parks and Wild-

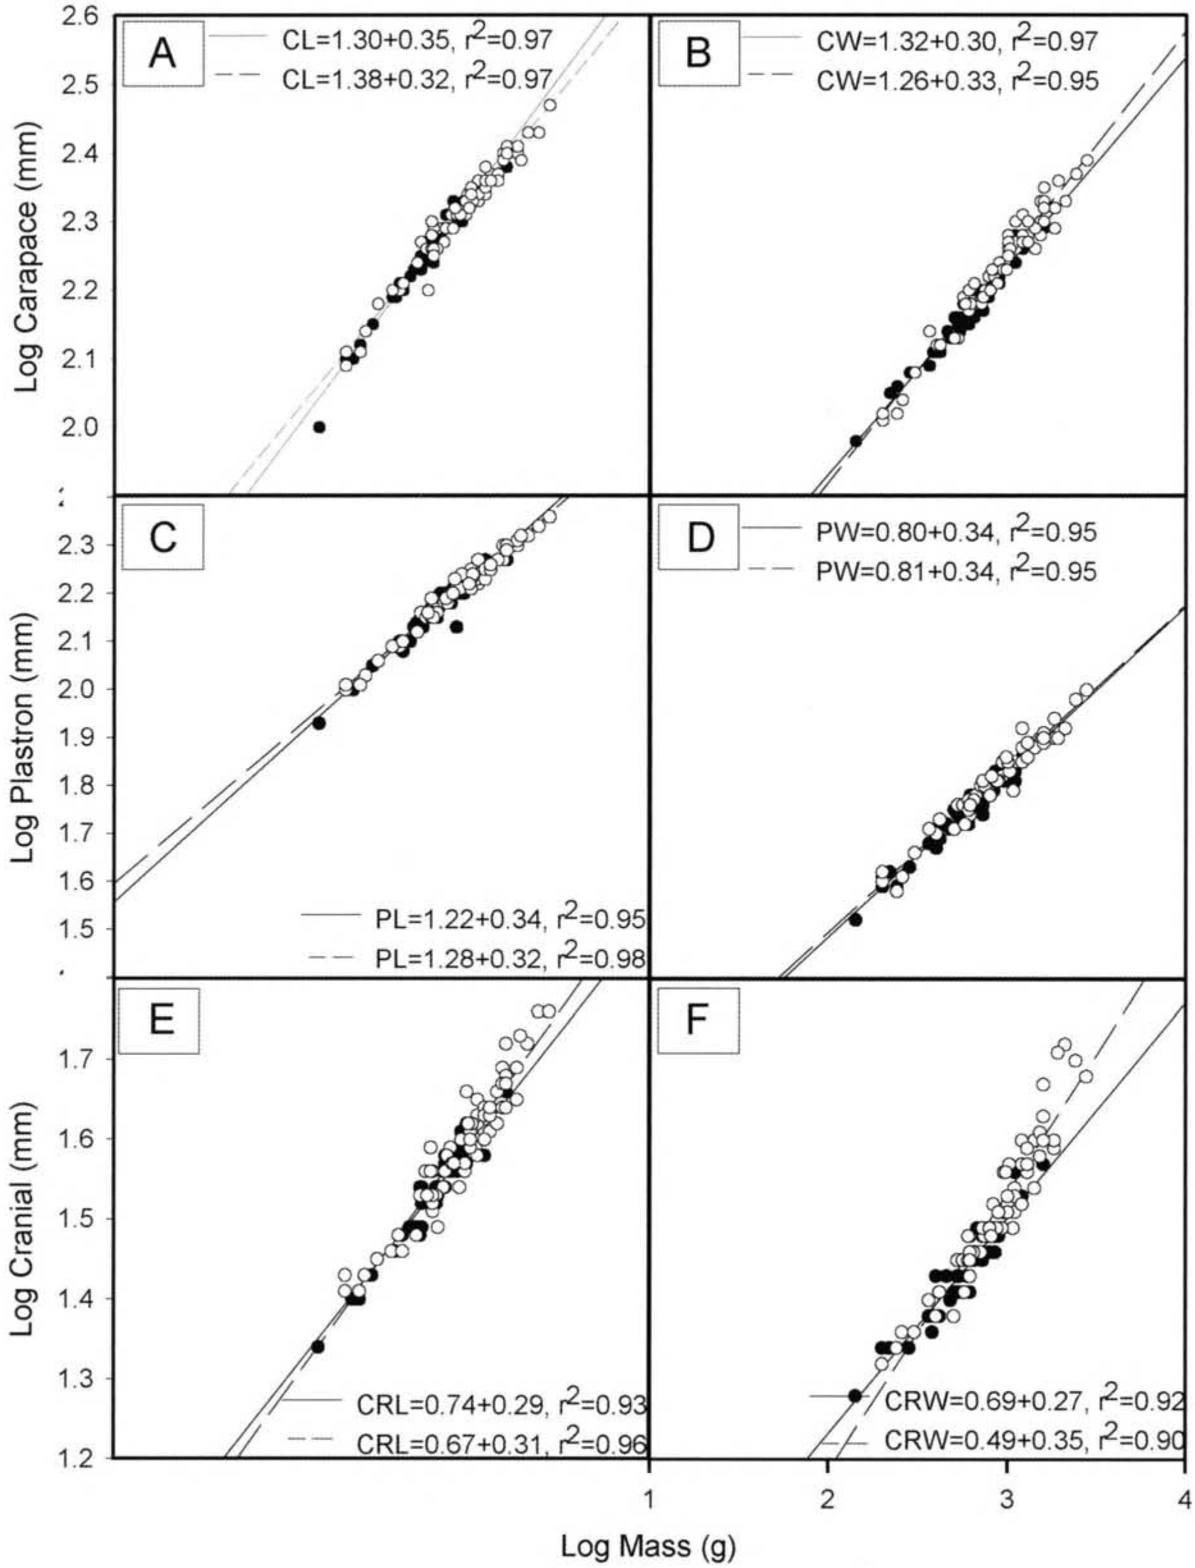

FIG. 2. Linear regressions of log carapace length (A), log carapace width (B), log plastron length (C), log plastron width (D), log cranial length (E), and log cranial width (F) on log body mass. The solid dots and lines represent males and the open dots and dashed lines represent females.

life Service. Thanks also to the following people for help in the field: David Poppi, Michael Heslop, Zubin Saleem, Jarle Jorgenson, and Steve Patane. Finally, thanks to David Blair for use of the James Cook University Rowing Club House. This work was conducted under Queensland National Parks & Wildlife Permit #F1/000415/01/SAB.

402 Kell Hall, 33 Gilmer St. SE, Unit 8, Atlanta, Georgia 30303-3088, USA

The native distribution of *Trachemys scripta elegans*, the red-eared slider, is limited to the Mississippi Valley from Illinois to the Gulf of Mexico (Ernst et al. 1994). For decades, *T. s. elegans* has been the most popular turtle in the pet trade worldwide. Furthermore, large numbers of adults have been shipped around the world as laboratory animals. From these sources, *T. scripta* has been introduced into many areas outside of its native range. Introduced populations have been reported worldwide in Japan, Germany, Israel, South Africa, and the Mariana Islands (Ernst et al. 1994), and in the U.S. in Michigan, Arizona, Hawaii, Pennsylvania, New Jersey, Washington D.C., and Virginia (Conant 1975; Ernst et al. 1994; Mitchell 1994). In Florida, introduced populations have been reported in Dade Co. (Wilson and Porras 1983), Orange Co. (Bancroft et al. 1983), and in Pinellas Co. at Coquina Key, Gulfport, Sawgrass Lake Park, Boyd Hill Park, and Eckerd College (Hutchison 1992; P. Meylan, pers. comm.; G. Heinrich, pers. comm.).

Hutchison (1992) reported a reproducing population of *T. s. elegans* at Fox Pond, Eckerd College. This species inhabits all Eckerd College campus ponds, which it shares with two native species, *Pseudemys floridana* and *P. nelsoni*. All of these ponds are connected through a storm sewage system. Fox Pond, a 1.21-ha body of water, is separated from Chapel Pond by a 1-m wide sidewalk, but the two ponds are connected by a storm pipe that runs under the sidewalk. Similarly, Fox Pond is connected to Front Gate Pond (0.567 ha) by a 415-m storm pipe, and to ELS Pond (0.243 ha) by a 455-m storm pipe. This report is an update of the status of the reproductively active population of *T. s. elegans* in Fox Pond.

Fox Pond was sampled 12 times over a 34-month period between September 1997 and December 1999 using funnel traps baited with sardines. Four 1.0 m by 0.75 m funnel traps (mesh size 2.5 cm) were placed near vegetation, approximately two-thirds submerged to allow captured turtles to surface. Captured turtles were marked by drilling the marginal scutes following the coding system of Gibbons (1988), and by insertion of AVID™ PIT tags. A variety of data were recorded from each turtle at each capture, but for the purposes of this paper we report only sex and straight midline plastron length (MPL). Adult female turtles were also x-rayed for the presence of eggs. The Jolly-Seber model (Pollock et al. 1990) was used to make 12 consecutive population and survivorship estimates. The population estimates were examined via regression analysis for evidence of population growth.

A total of 35 *T. s. elegans*, 20 males and 15 females, were captured 104 times over the 34-month study period. Female MPL ranged from 135–222 mm, with a mean ± SD of 183 mm ± 28 mm (Fig. 1). Male MPL ranged from 126–199 mm, and averaged 162 mm ± 19 mm (Fig. 1). Four females were gravid, with clutch sizes of 8, 9, 10, and 12 eggs.

Monthly population estimates ranged from 21.0 ± 15.9 to 54.7 ± 27.1 turtles (Fig. 2). Regression analysis demonstrated a slope of 0.532, which is significantly greater than zero ($t = 2.46$, $P < 0.05$), indicating a growing population. Survival rate was estimated as 97.5% for one of the monthly samples, and 100% for the remaining 11 samples, indicating that individuals are not being removed from the population.

Hutchison (1992) estimated the number of *T. s. elegans* in Fox Pond to be 25.7 individuals. The current estimate of 54.7 ± 27.1 individuals suggests an increase of greater than 100% in population size over the past eight years. By comparison, *T. scripta* population estimates for a newly constructed pond (0.3 ha) in Clay Co., Mississippi were determined to be one turtle in 1981, and 26 by 1983, an increase which may have been due to immigration (Parker 1990). The increase in the number of individuals in Fox Pond, which is similar to the increase at the Clay Co. Mississippi site, is at least in part due to immigration. Turtles captured in other campus ponds during an initial short-term trapping project have been recaptured in Fox Pond. I have documented the immigration of five turtles to Fox Pond from surrounding ponds, and the emigration of four turtles from Fox Pond to other campus ponds. Extensive trapping in the other campus ponds is necessary to accurately determine emigration/immigration frequencies.

Although the individuals inhabiting Fox Pond belong to a metapopulation, the continuous, slow increase in numbers sug-

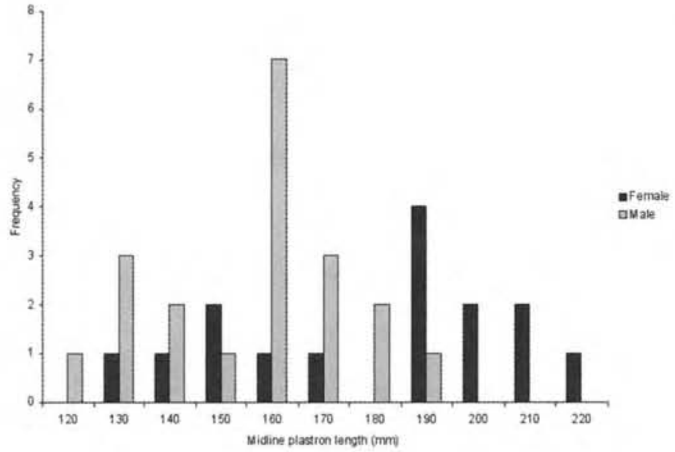

FIG. 1. Size frequency distribution of female and male *T. s. elegans* in Fox Pond.

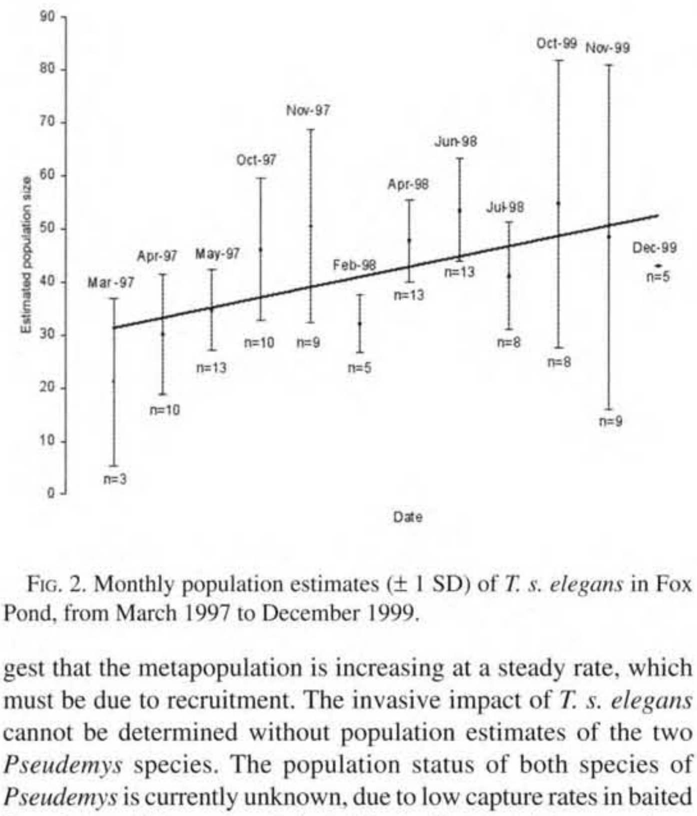

FIG. 2. Monthly population estimates (± 1 SD) of *T. s. elegans* in Fox Pond, from March 1997 to December 1999.

gest that the metapopulation is increasing at a steady rate, which must be due to recruitment. The invasive impact of *T. s. elegans* cannot be determined without population estimates of the two *Pseudemys* species. The population status of both species of *Pseudemys* is currently unknown, due to low capture rates in baited funnel traps that can be attributed to the fact that they are primarily herbivorous.

Acknowledgments—I thank Peter Meylan for his support and guidance throughout this study. Also, thanks to Ecology of Reptiles & Amphibians classes, and the Eckerd Herpetological Society for daily trap monitoring. I thank the Natural Sciences Collegium for their support, and Christopher Boykin and Matt Stone for guidance.

Determining the age of individual animals is extremely important for demographic, population dynamics, or life history studies of amphibians (Castanet and Smirina 1990; Hemelaar and van-Gelder 1980; Kusano et al. 1995; Ryser 1988; Smirina 1994). Mark-release-recapture and skeletochronology are generally used for estimating the age of amphibians (Castanet and Smirina 1990; Hemelaar 1981; Halliday and Verrell 1988; Kusano et al. 1995; Smirina 1994). Counting of growth layers in the phalangeal bones is a non lethal (therefore, ideal for live samples) and a good alternative method for mark-recapture (Coles et al. 2001).

The recent reviews on aging of amphibians reveal that most of the skeletochronological studies on the estimation of age and longevity of amphibians emerge from temperate areas (Castanet and Smirina 1990; Esteban et al. 1996; Halliday and Verrell 1988; Smirina 1994). In these species, the marked seasonality in the ambient temperature is known to result in the formation of distinct annual growth rings consisting in broader growth zones (corresponding to faster bone growth in warmer months) and lines of arrested growth or LAGs (corresponding to arrested bone growth in colder months). Alternately, amphibian species inhabiting constant warmer areas or tropics are expected to express the growth marks inconspicuously or less clearly owing to uninterrupted osteogenesis (Castanet and Smirina 1990; Guarino et al. 1998;

GEOGRAPHIC DISTRIBUTION

Instructions for contributors to Geographic Distribution appear in Volume 34, Number 2 (June 2003). Please note that the responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extensions unless a thorough literature review has been completed.

CAUDATA

AMBYSTOMA TALPOIDEUM (Mole Salamander). USA: ARKANSAS: PIKE Co: Hwy 301, 12.9 km SE Murfreesboro, Sec. 6 T9S R24W. 5 May 2002. Brian Caldwell. Henderson State University collection 1276. HOWARD Co: 5.2 km W of jct. Hwys 26 and 369, Sec. 30 T8S R27W. 27 April 2003. Brian Caldwell. Henderson State University collection 1297. Verified by Stan Trauth. First record for each county, both records are nonpaedomorphic larvae collected from swampy, lowland areas without fish. Howard Co. record extends known distribution in Arkansas in the West Gulf Costal Plain 63 km W from Clark Co. (Tumlison and Campbell 2002. Herpetol. Rev. 33:143–144) and 65 km SW from Garland Co. (Trauth et al. 1993. Proc. Arkansas Acad. Sci 47:154–156). Records also narrow the gap between previous records from Arkansas and those in Oklahoma (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 587 pp.).

EURYCEA LONGICAUDA LONGICAUDA (Long-tailed Salamander). USA: VIRGINIA: FAIRFAX Co: TNC Fraser Preserve. 10 June 1999. T. Akre. GMNH accession 49213, Georgia Museum of Natural History, University of Georgia. Verified by Carl H. Ernst. Adult of unknown sex found active at night on remains of an abandoned beaver lodge in a wet, intermittent stream ravine. County record. Carlin (1997. Herpetologica 53:206–217) reported that length of the mid-dorsal stripe discriminated *Eurycea guttolineata* from *E. longicauda* with 100% accuracy when compared to genetic analyses. However, Mitchell and Reay (1999. Atlas of Amphibians and Reptiles in Virginia. Virginia Dept. Game Inland Fisheries, Spec. Publ. No. 1:v + 122 pp.) considered individuals from streams in Fairfax Co. to be *E. guttolineata* with unusual phenotypes or offspring of hybridization with *E. longicauda*. This individual has no linear mid-dorsal pattern, complete or broken, though it was found ca. 50 km E of the nearest *E. longicauda* record, and within the distribution of *E. guttolineata* (Mitchell and Reay 1999, *op. cit.*).

ANURA

AGALYCHNIS CRASPEDOPUS. BRAZIL: AMAZONAS: Municipality of Castanho, km 22 on the BR319 road (3°21'16.8"S and 59°51'37.9"W). 19 February 2003. A. Pimentel Lima, V. M. L. Guida, and W Hödl. Amphibian and Reptile Collection of the Instituto Nacional de Pesquisas da Amazônia, Manaus. A male SVL 56.1 mm (INPA–10936) and female SVL 62.5 mm (INPA–10937). Verified from photographs by M. S. Hoogmoed. The pair was found in amplexus at 0500 h on a hollow log above a water-filled cavity, and stayed in the same place until 1200 h when we captured them. The species is known from Chicherota, Montalvo, and Limoncocha (Ecuador), and Rio Santiago, Tambopata Reserve, and Cocha Cashu (Peru) (Hoogmoed and Cadle 1991. Zoologische Mededelingen 65:129–142). Present record extends the range of this species and of the genus *Agalychnis* 1400 km to the east.

Submitted by **ALBERTINA PIMENTEL LIMA** and **VÂNIA MARÍLIA L. GUIDA**, Instituto Nacional de Pesquisas da Amazônia - INPA, C.P. 478, 69011-970 Manaus - Amazonas, Brazil, and **WALTER HÖDL**, Institute of Zoology, University of Vienna, Althanstrasse 14, A-1090 Wien, Austria.

APARASPHENODON BOKERMANNI. BRAZIL: SANTA CATARINA: Guaramirim Municipality, Atlantic Rain Forest (Restinga), 26°27'S, 49°00'W, 1 October 2002. Germano Woehl Jr. KU CT 11893–94. Verified by Jose Peres Pombal, Jr. First record for the state and Atlantic forests of southern Brazil.

BATRACHYLA ANTARTANDICA (Marbled Wood Frog), CHILE: REGION DE AYSEN: Reserva Nacional Katalalixar: Juan Stuven Island (47°55'S; 74°52'W), 10 February 2003. H. Díaz-Páez and S. Young. Adult male (36.8 mm SVL), Museo de Zoología Universidad de Concepcion, Concepcion (MZUC 27615). Verified by J. C. Ortiz. Specimen was collected in temperate, moist deciduous austral forest of Cipres (*Pilgerodendron uviferum*) and Ñirre (*Nothofagus antartandica*). Species inhabits austral forests of Chile and Argentina. In Chile the range extends from Cerro Mirador (Valdivia) to the El Correntoso River (Aysén). This is the first record for this island and extends the southern range of this species to the SW by ca. 315 km (Cei 1980, Amphibians of Argentina, Monit. Zool. Ital. [N.S.], Monogr. 2:i–xii + 1–609). Specimen was found calling inside mosses on small pond (1 m diam. and ca. 0.6 m deep), with several eggs around him, and a tadpole in the pond. This area is also inhabited by *Bufo variegatus* and *Eupsophus calcaratus*.

Submitted by **HELEN DÍAZ-PÁEZ** and **SUE YOUNG,** Laboratorio de Herpetología, Facultad de Ciencias Naturales y Oceanográficas, Universidad de Concepción. Casilla 160-C, Concepcion, Chile, and Durrell Institute of Conservation and Ecology (DICE), University of Kent, Canterburry, UK CT2.

BUFO DEBILIS INSIDIOR (Western Green Toad). USA: NEW MEXICO: SIERRA Co: White Sands Missile Range, earthen tank at Martin Ranch hdqs., ca. 45 air mi NE Truth or Consequences, T10S R4E NW1/4 Sec 6. 31 July 1997. L. K. Kamees and D. W. Burkett. University of New Mexico Museum of Southwestern Biology (MSB 60800). Verified by B. G. Fedorko. County record (Degenhardt et al. 1996. The Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque, xix + 431 pp.).

Submitted by **LARRY K. KAMEES** and **DOUGLAS W. BURKETT,** MEVATEC Corporation, P.O. Box 399, White Sands Missile Range, New Mexico 88002, USA.

BUFO PUNCTATUS (Red-spotted Toad). USA: NEW MEXICO: RIO ARRIBA Co: Artesian Spring, Arroyo del Cobre, 7 mi (11.2 km) NNW of Abiquiu, ca. 2040 m (36°18'29"N, 106°21'16"W). 12 June 1998. John E. Ubelaker. University of New Mexico Museum of Southwestern Biology (MSB 66533–36). Verified by William Degenhardt. New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque, xix + 431 pp.). Extends the distribution by ca. 45 km N of Pajarito Canyon, Los Alamos Co., the nearest verified locality (MSB 36397).

CHIASMOCLEIS HUDSONI (NCN). VENEZUELA: ESTADO AMAZONAS: non-flooded rainforest near the confluence of the Pamoni River with the Casiquiare River, 2°50'N, 65°43'W, ca. 80 m elev., inside a soil profile pit in early morning hours after a rainy night. W. Schargel. 30 February 2000. Museo de Historia Natural La Salle, Caracas, Venezuela (MHNLS 16112). Verified by C. Señaris. Second state record, and first voucher specimen in a Venezuelan museum. The species is distributed through the Guianas (Surinam, French Guiana, Guyana; Lescure and Marty 2000. Atlas des Amphibiens de Guyane. Museum National d' Histoire Naturelle, Paris) and Venezuela. *Chiasmocleis hudsoni* was reported (without voucher number) from Venezuela from the base of Serranía de la Neblina, a few km from the border with Brazil, and ca. 110 km from Colombia's border (Zweifel 1986. Amer. Mus. Novitates 2847:1–24). This species has not been reported from either of these countries. The Neblina locality is 200 km S of the Casiquiare record.

Submitted by **CÉSAR LUIS BARRIO AMORÓS**, Fundación ANDÍGENA, Apartado 210, 5101–A Mérida, Venezuela (e–mail: atelopus@andigena.org), and **WALTER E. SCHARGEL**, Department of Biology, University of Texas at Arlington, Box 19498, Texas 76019, USA (e–mail: wschargel@yahoo.com).

CHIRIXALUS NONGKHORENSIS (NCN). MALAYSIA: PENINSULAR MALAYSIA: Kedah (northern state): Ulu Muda forest reserve (06°00'N, 100°58'E; near political border of Thailand). 21 April 2003. Boo Liat Lim et al. Raffles Museum of Biodiversity Research: Zoological Reference Collection (ZRC.1.10802, SVL 26.9 mm; 10803, SVL 27.2 mm). Verified by Kelvin K. P. Lim. New country record and southerly range extension for the species, which is known from Vietnam, Laos, Cambodia, Myanmar, and Thailand (Orlov et al. 2002. Russian J. Herpetol. 9[2]:81–104). Also first representative of the genus *Chirixalus* for the country.

Submitted by **TZI MING LEONG**, Department of Biological Sciences, National University of Singapore, Singapore 119260 (e–mail: scip0132@nus.edu.sg), and **BOO LIAT LIM**, Department of Wildlife and National Parks (Peninsular Malaysia), Km 10, Jalan Cheras, 561000 Kuala Lumpur, Malaysia.

COLOSTETHUS HUMILIS (Sapito Niñera Humilde). VENEZUELA: ESTADO TÁCHIRA: Doradas, Uribante rivers (precise locality not stated), 1500 m. 18 June 1985. Proyecto Uribante-Caparo. Colección de Vertebrados, Universidad de los Andes (CVULA 3790). Verified by A. Orellana. First state record, southernmost and westernmost for the species, ca. 215 km from the type locality, at Boconó, Trujillo state (Rivero 1978. Mem. Soc. Cien. Nat. La Salle, 38 [109]:95–111). The new record is in the same Andean piedmont considered to be an Amazonian corridor (Barrio-Amorós 1998. Acta Biol. Venez. 18[2]:1–93).

Submitted by **CÉSAR LUIS BARRIO-AMORÓS,** Fundación AndígenA, Apartado Postal 210, Mérida 5101-A, Venezuela (e-mail: cesarlba@yahoo.com), and **JOAN GARCIA-PORTA**, Societat Catalana d' Herpetologia, Museu de Zoologia, passeig Picasso s/n. 08003 Barcelona, Spain.

EUPSOPHUS CALCARATUS (Chiloé Island Ground Frog). CHILE: REGION DE AYSEN: Reserva Nacional Katalalixar: Merino Jarpa Island (47°52'S; 73°51'W). 1–2, 4 February 2003. H. Díaz-Páez and S. Young. Museo de Zoología Universidad de Concepción, Concepción (MZUC 27597–98, 27602–03). Reserva Nacional Katalalixar: Berta Island (47°49'S; 73°47'W). 3 February 2003. H. Díaz-Páez and S. Young. (MZUC 27600–01). Reserva Nacional Katalalixar: Juan Stuven Island (47°55'S; 74°52'W). 10–11 February 2003. H. Díaz-Páez and S. Young. (MZUC 27616–17, 27621–22). All specimens verified by J. C. Ortiz. The individuals were collected in temperate, moist, austral forest of Mañio (*Podocarpus nubigena*), Cipres (*Pilgerodendron uviferum*) and Tepú (*Tepualia stipularis*). Species inhabits austral forests of Chile and Argentina. It ranges from Valdivia to Wellington Island (49°08'S; 74°26'W) in Puerto Edén, Chile to Tromen Lake and Puelo Lake in Argentina (Nuñez et al. 1999. Studies of Neotropical Fauna and Environment. 34:150–155). First record for these islands and the westernmost record for the species.

Submitted by **HELEN DÍAZ-PÁEZ, PATRICIA BERRIOS,** Laboratorio de Herpetología, Facultad de Ciencias Naturales y Oceanográficas, Universidad de Concepción. Casilla 160-C, Concepción, Chile, and **SUE YOUNG,** Durrell Institute of Conservation and Ecology (DICE), University of Kent, Canterbury, UK CT2.

GASTROTHECA OVIFERA (Marsupial Frog). VENEZUELA: ESTADO FALCÓN. Municipio Jacura, Cerro Los Caracoles, 10º52'17"N, 69º01'39"W. 1000 m elev. 4 September 2002. J. Latke. Museo de la Estación Biológica de Rancho Grande, Ministerio del Ambiente y de los Recursos Naturales (EBRG 4618–19). Verified by R. Rivero. First state record (Mijares-Urrutia and Arends 2000. Smithson. Herpetol. Infor. Serv. 123, 30 pp.). Northernmost and westernmost record for the species (Barrio 1999. Herpetol. Rev. 30:106.

Submitted by **JESÚS MANZANILLA** and **DINORA SÁNCHEZ**, Museo del Instituto de Zoología Agrícola, Facultad de Agronomía, Universidad Central de Venezuela, Aragua, Venezuela (e-mail: manzanillaxxi@hotmail.com; sanchezdinora@hotmail. com).

HYLA CRUZI (NCN). BOLIVIA: DEPARTAMENTO SANTA CRUZ: PROVINCIA VELASCO: 14 km (road) W of La Mechita (close to the border of P. N. Noel Kempff Mercado), 14°33'S, 61°29'W, 270 m elev. 7 December 1998. Stefan Lötters and Steffen Reichle. Verified by Wolfgang Böhme. Zoologisches Forschungsinstitut und Museum Alexander Koenig, Bonn, Germany (ZFMK 72672–673). First record for the country. Westward range extension of ca. 1400 km. The species was formerly known only from the type locality (16°38'S, 48°38'W) and a nearby location in the Estado de Goiás, Brazil (Pombal and Bastos 1998. Bol. Mus. Nac., N.S. Zool. Rio de Janeiro 390:1–14). This is the third locality known for the species. The range extension documented is remarkable, but not unexpected from a biogeographical point of view, since several other central Brazilian anuran species occur at the aforementioned Bolivian locality (e.g., *Hyla albopunctata, H. multifasciata, Physalaemus centralis*). The two males from Bolivia (SVL 19.4 and 19.6 mm) agree perfectly with the original species description. It seems very probable that *Hyla cruzi* also inhabits the area in between these known localities, since minute species of *Hyla* are often overlooked or misidentified.

Submitted by **JÖRN KÖHLER**, Zoologisches Forschungsinstitut und Museum Alexander Koenig, Adenauerallee 160, 53113 Bonn, Germany; e–mail: j.koehler.zfmk@uni-bonn.de.

HYLOMANTIS GRANULOSA (NCN). BRAZIL: PERNAMBUCO: Timbaúba, Usina Cruangi, in forest adjacent to Engenho Água Azul (7°36'S, 35°22'W, 300–500 m. elev). 24 May 1999. A. Carnaval and S. Roda. Coleção de Anfíbios, Laboratório de Anfíbios e Répteis, Instituto de Biologia, Universidade Federal do Rio de Janeiro (ZUFRJ 7879). Jaqueira, Usina Frei Caneca, in forest at Mata da Serra do Quengo (8°42'S, 35°50'W, 550–750 m elev). 7 June 1999. A. Carnaval and J. Vicente Filho (ZUFRJ 7925). Brejo da Madre de Deus, in forest at Sítio Bituri (8°12'S, 36°24'W, 850–1050 m. elev). 10 June 2001. M. Silva and A. Carnaval (ZUFRJ 8672). São Lourenço da Mata, Estação Ecológica do Tapacurá, in forest at Mata do Toró (8º07'S, 34º60'W, 10–100 m. elev.). 28 May 2000. E. Santos. Coleção Eugenio Izecksohn, Departamento de Biologia Animal, Instituto de Biologia, Universidade Federal Rural do Rio de Janeiro (EI 9589). All verified by Carlos A. G. Cruz. The species was previously known from its type locality only (Horto Zoobotânico Dois Irmãos, Recife, Pernambuco, 8°00'S, 34°57'W, 10–100 m elev.) (Cruz 1988. Arq. Univ. Fed. Rur. Rio de J. 11:39–44; Cruz 1991. Rev. Bras. Biol. 50:709–726). These records extend the species' known distribution ca. 60 km northward, 70 km southward, and 125 km westward within the state of Pernambuco, and broadens its altitudinal range.

Submitted by **ANA CAROLINA O. Q. CARNAVAL**, Field Museum and Committee on Evolutionary Biology, University of Chicago, 1025 East 57th Street, Culver Hall 402, Chicago, Illinois 60637, USA, **OSWALDO L. PEIXOTO**, Universidade Federal Rural do Rio de Janeiro, Instituto de Biologia, Departamento de Biologia Animal, BR 465, Seropédica, RJ, CEP 23851-970, Brazil, and **EDNILZA M. OSTEOPILUS SEPTENTRIONALIS (Cuban Treefrog). USA: FLORIDA: LEVY CO: Fowlers Bluff, County Road 347 ca. 30 km N of Cedar Key, on house at 4111 NW 154th Avenue (29.388°N, 83.030°W). 26 May 2003. Steve Barlow. Verified by Kenneth L. Krysko. Florida Museum of Natural History, University of Florida, Gainesville (UF 137016). One adult female (92 mm SVL) collected by local resident and brought to Lower Suwannee National Wildlife Refuge (LSNWR) headquarters. The resident reported that he has seen these frogs for the past several years. This apparently is the first published record of *O. septentrionalis* from Levy Co., but there are specimens from Cedar Key (Levy Co.) dating to 2001. Three frogs from Cedar Key, all road-killed specimens, are in the UF herpetology collection. They were collected by Dale Henderson on 4 November 2001 (UF 133927), 29 June 2002 (UF 133928), and 13 July 2002 (UF 133929). It is likely that a breeding population is established at Cedar Key. The Fowlers Bluff record extends the known range of *O. septentrionalis* on Florida's Gulf coast ca. 30 km N of Cedar Key in Levy Co. and ca. 80 km N of a published record for Citrus Co. (Meshaka 1996. Herpetol. Rev. 27:37–40).

Submitted by **STEVE A. JOHNSON**, **JENNIFER S. STAIGER**, **WILLIAM J. BARICHIVICH** , US Geological Survey, Florida Integrated Science Center, 7920 NW 71st Street, Gainesville, Florida 32653, USA, and **STEVE BARLOW**, US Fish and Wildlife Service, Lower Suwannee National Wildlife Refuge, 16450 NW 31st Place, Chiefland, Florida 32626, USA.

PHYLLOMEDUSA PALLIATA (NCN). BOLIVIA: DEPARTMENTO SANTA CRUZ: PROVINCIA ICHILO : La Chonta, Parque Nacional Amboró (17°39'36"S, 63°42'6.6"W). R. O. de Sá and J. M. Padial. 22 April 2003. One adult and two juveniles collected on low vegetation (ca. 1.5 m above ground) in an Amazonian rainforest. Museo de Historia Natural Noel Kempff Mercado, Santa Cruz (NKA 6502). Verified by S. Reichle. First record from Departamento Santa Cruz and southernmost record for the species, enlarges known distribution ca. 500 km NW (airline) from the nearest record: Valle Totaizal (14°38'S,66°18'W, Reichle and Köhler 1996. Herpetofauna 18[101]:32–34).

RANA SYLVATICA (Wood Frog). USA: GEORGIA: UPSON Co: Woodland pool near confluence of Turkey Creek and Flint River at Sprewell Bluff, 11.3 km W of Thomaston. Carlos Camp and Alex Pyron. Eggs collected 23 February 2003 and raised to metamorphosis. Verified by E. McGhee. Two newly metamorphosed frogs deposited in Georgia Museum of Natural History (GMNH 49216–17). Site is surrounded by steep bluffs associated with Flint River with mesic hardwoods of oak (*Quercus* spp.) and beech (*Fagus grandifolia*) on lower slopes. Upper slopes and ridge-tops with xeric mixed forest of post oak (*Quercus stellata*) and long-leaf pine (*Pinus palustris*). Site is on lower Piedmont < 30 km N of Fall Line. Represents 145 km southerly extension of range in Georgia (Rubio et al. 2003. Herpetol. Rev. 34:78–80) and southernmost record for species (Davis and Folkerts 1986. Brimleyana 12:29–50).

Submitted by **CARLOS D. CAMP** and **R. ALEX PYRON**, Department of Biology, Piedmont College, PO Box 10, Demorest, Georgia 30535, USA.

RANA SYLVATICA (Wood Frog). USA: KENTUCKY: CAMPBELL Co: Melbourne, NE intersection Rt. 8 and Anderson Rd. 26 June 2002. John Ferner, Brian King, and Eric Chapman. Thomas More College Herpetology Collection (TMC A201). Verified by Jeffrey G. Davis. New county record based on Conant and Collins (1991, A Field Guide to Reptiles and Amphibians of Eastern and Central North America. Houghton Mifflin Co. Boston, Massachusetts, 450 pp.).

Submitted by **JOHN W. FERNER**, **ERIC CHAPMAN**, **BRIAN KING**, and **PAUL KRUSLING**, Department of Biology, Thomas More College, Crestview Hills, Kentucky 41017, USA.

TESTUDINES

CHELYDRA SERPENTINA (Snapping Turtle). USA: NEW MEXICO: TORRANCE Co: DOR north side of Interstate 40, near Osita Draw, 5.7 km W Clines Corners, ca. 2100 m elev. (35°00'16"N, 105°43'52"W). 1 June 2003. Tom Giermakowski and Aaron Lamb. Verified by Charles Painter. University of New Mexico Museum of Southwestern Biology (MSB 66531). New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. of New Mexico Press, Albuquerque, xix + 431 pp.). Documents presence at a relatively high altitude water body outside of both the Pecos and Rio Grande drainages (to the east and west, respectively). It is unlikely this specimen was a released individual given the locality and proximity to water sources.

Submitted by **TOM GIERMAKOWSKI** (e-mail: tomas@unm.edu) and **AARON LAMB** (e-mail: awlamb5@yahoo.com), Museum of Southwestern Biology, MSC03 2020, University of New Mexico, Albuquerque, New Mexico 87131–0001, USA.

CHELYDRA SERPENTINA SERPENTINA (Eastern Snapping Turtle). USA: TEXAS: MARION Co: 9.7 km NW Jefferson off FM 728, on Berea 3. 12 June 2003. D. I. Moore. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 27919). Verified by Stanley E. Trauth. New county record completely filling hiatus in northeastern Texas of the Arkansas-Louisiana-Texas junction (Allen and McAllister. 2001. Herpetol. Rev. 32:191; Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Univ. Press, College Station. 421 pp.). Also reported previously from adjacent Caddo Parish, Louisiana (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. LSU Press, Baton Rouge. 300 pp.).

Submitted by **DAWN I. MOORE** and **CHRIS T. McALLISTER,** Department of Biology, Texas A&M University-Texarkana, Texarkana, Texas 75505, USA; e-mail: chris.mcallister@tamut.edu.

TRACHEMYS GAIGEAE (Big Bend Slider). USA: New Mexico: DONA ANA Co. Rio Grande, ca. 13 km SE of Hatch (T19S, R2W, SE1/4 Sec 27). 11 May 2003. Michael (Mischa) Larisch and Laura J. Larisch. Digital photograph (UTEP 18838). Verified by Douglas

W. Burkett and C. W. Painter. First record for Dona Ana County and southernmost record for New Mexico (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque, xix + 431 pp.). The turtle was caught by fishing in a small pool in the river.

Submitted by **MICHAEL (MISCHA) LARISCH** and **LAURA J. LARISCH**, 517 Cain Drive, Silver City, New Mexico 88061, USA; e–mail: larischm@yahoo.com.

CROCODYLIA

CROCODYLUS ACUTUS (American Crocodile). USA: FLORIDA: Glades Co.: ca. 10.3 km E of Venus (27°04.513'N, 81°14.927'W). 10 May 2000. Kevin M. Enge and Rodney T. Felix. Verified by Paul E. Moler. UF 137132 photographic voucher. New county record and extends the species range ca. 109 km inland from the Atlantic Coast. *Crocodylus acutus* that were presumably released individuals have been reported farther N from Vero Beach, Indian River Co., on the Atlantic Coast and Lake Tarpon, Pinellas Co., on the Gulf Coast (Behler 1978. S. Florida Res. Cent. Rep. T-509, Homestead, Florida. 94 pp.). Juvenile (90 cm TL) captured in a freshwater ditch connecting Jerry Marsh to the headwaters of Gator Slough, which drains into Fisheating Creek. In the 1970s, *C. acutus* frequently escaped from Gatorama (Behler, *op cit.*; Campbell 1979. American Crocodile Recovery Plan. U.S. Fish and Wildl. Serv. 24 pp.), an alligator farm and tourist attraction on US Hwy 27 near Palmdale located ca. 20 km (> 27 km by water) S of the capture site. Gatorama successfully bred and once housed ca. 200 *C. acutus*, but only ca. 45 were observed in 1977 (Behler, *op cit.*). *Crocodylus acutus* up to 4 m long were captured or observed in Fisheating Creek in the late 1970s, and females were observed nesting beyond Gatorama's unburied, chain-link perimeter fence (Tim Breault, pers. comm.). All *C. acutus* at Gatorama were thought to have come from Jamaica (Behler, *op cit.*; Campbell, *op cit.*), but mtDNA sequence data indicate that this specimen had a Florida mother (Michael J. Forstner, pers. comm.). Because the species is endangered and the specimen was of Florida origin, it was released into Fisheating Creek. Fisheating Creek drains into Lake Okeechobee, where *C. acutus* might have occurred infrequently in the past (Willoughby 1898. Across the Everglades: A Canoe Journey of Exploration. J. B. Lippincott Company, Philadelphia, Pennsylvania, 192 pp.; Kushlan and Mazzotti, *op cit.*; Romulus Whittaker, pers. comm.). This specimen was captured ca. 8 km N of the 17°C average January air isotherm, which occurs farther S inland and is considered to generally represent the northern range extent of this tropical species (Kushlan and Mazzotti 1989. J. Herpetol. 23:1–7). The northern extent of the historical nesting distribution was apparently on the Atlantic Coast at Lake Worth, Palm Beach Co. (Campbell, *op cit.*), ca. 47 km S of the capture site. *Crocodylus acutus* are occasionally found up to 50 km inland (Paul E. Moler, pers. comm.), and individuals are capable of making long-distance movements exceeding 100 km (Kushlan and Mazzotti, *op cit.*), but the small size of this specimen suggests that a breeding population consisting of at least one native female might occur in the Fisheating Creek area. Alternately, the specimen could be an escapee from some facility.

Submitted by **KEVIN M. ENGE**, Florida Fish and Wildlife Conservation Commission, Joe Budd Wildlife Field Office, 5300 High Bridge Road, Quincy, Florida 32351, USA.

LACERTILIA

ANOLIS ORTONII (NCN). VENEZUELA: ESTADO BOLÍVAR: Forest at the left margin of Cucurital River (06°00'32"N, 62°46'52"W), 390 m elev. 16 April 1999. E. La Marca. Museo de Historia Natural La Salle, Caracas (MHNLS 14412). Forest at the left margin of Cucurital River, ca. 1550 m from the shores of the small blackwater stream known as Orowapá, at the ornithology base camp "Pipra 2" (5°55'00"N, 62°43'50"W), 450 m elev. 4 February 2000. C. Molina. (MHNLS 14904). 2 May 2002. V. Romero. (MHNLS 15716–17). Indigenous Pemon trail, ca. 200 m from the shores of caño Zamuro, Canaima National Park (6°18'13"N, 62°49'47"W), 400 m elev. 22 July 2002. C. Molina. MHNLS 15815. All verified by G. Rivas. *Anolis ortonii* was first listed for Venezuela by La Marca (1997. Vertebrados Actuales y Fósiles de Venezuela. Serie Catálogo Zoológico de Venezuela. Vol. 1. Museo de Ciencia y Tecnología de Mérida, Venezuela) based on a misidentification. The MHNLS specimens are the first definite records for Venezuela (Peters and Donoso-Barros 1970. Catalogue of the Neotropical Squamata: Part II. Lizards and Amphisbaenians. U.S. Natl. Bull. 297:62; Hoogmoed 1973. Notes on the Herpetofauna of Surimam IV. The Lizards and Amphisbaenians of Surinam. Junk, The Hague; Avila-Pires 1995. Lizards of Brasilian Amazonia [Reptilia: Squamata], Zool. Verh. Leiden 299:1–706; Gorzula and Señaris 1999. Contribution to the Herpetofauna of the Venezuelan Guayana I. A Data Base. Scientiae Guaianae 8: xviii + 1–268, 32 pls.). The new records extend the known range more than 450 km W of the nearest reported locality, near the confluence of the Cuyuní and Essequibo rivers (Avila-Pires, *op. cit.*: 95, map 25), an area between Venezuela and Guyana.

Submitted by **CÉSAR MOLINA**, Museo de Historia Natural La Salle, Sección de Herpetología, Apartado Postal 1930, Caracas 1010–A, Venezuela (e–mail: washaema@hotmail.com), **ENRIQUE LA MARCA**, Laboratorio de Biogeografía, Universidad de Los Andes, Mérida, Venezuela (e–mail: lamarca1@telcel.net.ve), and **CELSA SEÑARIS**, Museo de Historia Natural La Salle, Sección de Herpetología, Apartado Postal 1930, Caracas 1010-A, Venezuela (e–mail: celsa35@hotmail.com).

ASPIDOSCELIS COSTATA COSTATA (Balsas Basin Whiptail). MÉXICO: TLAXCALA: Municipality of Nativitas near Cacaxtla ruins (19°14'33"N, 98°20'40"W), 2293 m elev. 20 May 2000. Lorena López-González and Felipe Rodríguez-Romero. Colección Nacional de Anfibios y Reptiles, Universidad Nacional Autónoma de México (IBH–13795). Verified by Fausto R. Méndez. First record for Tlaxcala (Duellman and Zweifel 1962. Bull. Amer. Mus. Nat. Hist. 123:159–210; Maslin and Secoy 1986. Contrib. Zool. Univ. Colorado Mus. No. 1:1–60).

CROTAPHYTUS COLLARIS COLLARIS (Eastern Collared Lizard). USA: OKLAHOMA: LeFlore Co: 14 km W Choctaw Historic State Line Monument site, off OK St. Hwy 1 (Talimena Scenic National Byway), Rich Mountain, 795 m elev. 27 May 2003. C. T. McAllister. Arkansas State University Museum, Herpetological Collection (ASUMZ 27979–80, adult male and female). Verified by S. E. Trauth. First record from Rich Mountain; previously reported from other more distant sites in LeFlore County (Webb 1970. Reptiles of Oklahoma. Univ. Oklahoma Press, Norman, Oklahoma, 370 pp; Secor and Carpenter 1984. Oklahoma Herpetol. Soc. Spec. Publ. 3:1–57; McGuire 1996. Bull. Carnegie Mus. Nat. Hist. 32:1–143; Oklahoma Biological Survey's Distribution of Oklahoma Amphibians and Reptiles by Recorded Sightings, DOKARRS [http://www.biosurvey.ou.edu/dokasdesc.html]). Extends the known range 7.7 km SSW from the Spring Mountain, LeFlore County, Oklahoma site (Webb 1970, *op cit.* p. 152). In this part of their range, valleys do not provide sufficient habitat to support the species, effectively creating isolated mountain island populations. Trauth et al. (In press. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville) reported an historical record for *C. c. collaris* from a "valley" site near the Eagleton and Rich Mountain Communities, in adjacent Polk County, Arkansas. This site is ca. 9 km due E of the site herein. However, no lizards have been found on the Arkansas side of Rich Mountain during recent surveys.

Submitted by **CHRIS T. McALLISTER** (e-mail: chris.mcallister@tamut.edu), Department of Biology, Texas A&M University-Texarkana, Texarkana, Texas 75505, USA, and **JAMES T. McALLISTER, III**, Brookhaven College, 3939 Valley View Lane, Farmers Branch, Texas 75244, USA.

HELODERMA HORRIDUM HORRIDUM (Mexican Beaded Lizard). MÉXICO: MÉXICO: Municipio de Luvianos, Barranca Peña Blanca (18º51'45"N, 100º18'18"W), 1529 m elev. 26 Aug 2002. A. Hernández Saint-Martin. Colección Nacional de Anfibios y Reptiles del Instituto de Biología, Universidad Nacional Autónoma de México (IBH 13986). Verified by Fausto R. Méndez de la Cruz. First valid record for the state of México. An earlier specimen (MVZ 16434) has locality data attributing it to District Temascaltepec, Tejupilico, Mexico, Mexico (actually Temascaltepec and Tejupilco are separate municipalities). However, Bogert and Martín del Campo (1956. Bull. Amer. Mus. Nat. Hist. 109:1–238) restricted it, without comment, to Tejupilco, México.

HEMIDACTYLUS TURCICUS (Mediterranean House Gecko). USA: ARKANSAS: Washington Co.: greenhouse and physics buildings on the campus of the University of Arkansas, junction of Duncan and Dickson streets, Fayetteville, Arkansas (36°03'59"N, 94°10'15"W). 5 September 2001. Glenn J. Manning and Jeffrey T. Briggler. University of Arkansas Museum (adult: ARK 2001–10–1 and juvenile: ARK 2001–10–2). Verified by James M. Walker. Three juvenile geckos were first seen in the physics building on 18 October 1999. A juvenile gecko was collected in October 2000 on the sidewalk near the physics building. On 5 September 2001, investigation of physics building and surrounding buildings resulted in the observation of three adult geckos on the outside of the greenhouse (one was taken for a voucher), and two geckos on the outside of the physics building (one juvenile and one adult). The juvenile was taken as a voucher. The adult had a SVL of 50 mm and weighed 3.0 g, and the juvenile had a SVL of 26 mm and weighed 0.5 g. This record extends the range of *H. turcicus* ca. 97 km N from the nearest known population at University of Arkansas–Fort Smith (formerly Westark Community College), Sebashian Co. (Paulissen and Buchanan 1990. Herpetol. Rev. 21:22). It has been determined that this is an established population that was introduced through the greenhouse.

Submitted by **GLENN J. MANNING**, Department of Biology, University of Arkansas, 416 SCIE, Fayetteville, Arkansas 72701, USA (e-mail: gmannin@uark.edu), and **JEFFREY T. BRIGGLER**, Missouri Department of Conservation, Jefferson City, Missouri 65102, USA (e–mail: briggj@mail.conservation.state.mo.us).

LEIOCEPHALUS CARINATUS (Northern Curly-tailed Lizard) USA: FLORIDA: Lee Co.: Cape Coral: on patio at 1434 SE 20th Street (26°36'51"N, 81°56'43"W). 10 July 2003. T. S. Campbell and G. S. Klowden. Verified by Kenneth Krysko, University of Florida Museum of Natural History (UF 137383). County record. One female collected, numerous males and females observed on driveways and landscaping at nearly every residence on the 1400 block of 20th Street, two observed on the 1300 block of 20th Street, and one seen on the 1400 block of SE 19th Lane. First record of this species on the west coast of Florida, extending its range southwest ca. 100 km from populations established in Highlands County (Layne 1987. Herpetol. Rev. 18:20) and west and northwest ca. 200 km from the populations established in Palm Beach, Miami-Dade, and Martin counties (King and Krakauer 1966. Quart. J. Florida Acad. Sci 29:144–154; Wilson and Porras 1983. Univ. Kansas Mus. Nat. Hist. Spec. Publ. 9:1–89; Hauge and Butterfield 2000. Herpetol. Rev. 31:53).

NOROPS BIPORCATUS (NCN). VENEZUELA: ESTADO MÉRIDA: Hacienda Mesa de Los Negros, Las Virtudes, 600 m elev. Museo de Historia Natural La Salle, Caracas, Venezuela (MHNLS 8012 and 8491, both adult females, each with one enlarged oviductal egg). S. Boher. 30 December 1979 and 15 August 1980. Verified by C. R. Molina. First state record and easternmost for the species, extending its distribution 170 km NE from the nearest locality, La Fría in Táchira state (Williams 1966. Breviora 239:1–14). This green anole has a wide distribution in Central America, from México to Panamá (Savage 2002. The Amphibians and Reptiles of Costa Rica: a Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.) and extending to northern South America, through Chocoan Colombia and Ecuador, west of the Andes, but also extending to northeast Colombia, reaching the Maracaibo Basin in Venezuela. In Venezuela the species was formerly known from two localities in two different states, Zulia (Perijá: Kasmera and misión El Tokuko) and Táchira (see Williams 1966, *op. cit.*).

Submitted by **GILSON RIVAS FUENMAYOR**, Museo de Historia Natural La Salle, Apartado Postal 1930, Caracas 1010-A, Venezuela (e-mail: anolis30@hotmail.com), and **CÉSAR LUIS BARRIO-AMORÓS**, Fundación AndígenA, Apartado Postal 210, Mérida 5101-A, Venezuela (e-mail:cesarlba@yahoo.com).

SCELOPORUS OCHOTERENAE (Ochoterena's Spiny Lizard). MÉXICO: PUEBLA: Mixteca Poblana, 4.6 km SE Izúcar de Matamoros, 1100 m elev. 17 July 1955. F. G. Thompson. UMMZ 112578. 1.6 km E Raboso. Additional records for this species (e.g., RKU 37736, LSU 6417, EBUAP 2044–45, MZFC 6845–46) exist, all within 10 km of the first locality. First records for the state, extending its range eastward ca. 36 km from 2 km S of Jonacatepec, Morelos (TCWC 6529, 6547). All the above Puebla localities are situated on the extreme western edge of the state, and represent the northwestern extreme of the known range of the species (personal data of HMS).

SCELOPORUS TORQUATUS MELANOGASTER (Black-bellied Crevice Swift). MÉXICO: MÉXICO: Municipio de Polotitlán, 1.5 km W of Taxhié (20°13'49"N, 99°54'36"W), 2191 m elev. 29 October 2002. Oswaldo Hernández, Felipe Rodríguez, and Gustavo Casas. Colección Nacional de Anfibios y Reptiles del Instituto de Biología, Universidad Nacional Autónoma de México (IBH 13968–70). Verified by Fausto R. Méndez de la Cruz. First record for the state of México (Camarillo and Smith 1992. *In* Strimple and Strimple [eds.], Contributions in Herpetology, pp. 39–41. Greater Cincinnati Herpetological Society, Cincinnati, Ohio; Casas et al. 1997. Anfibios y Reptiles, Lista Taxonómica de los Vertebrados Terrestres del Estado de México. Univ. Autón. Edo. México, Cienc. Tec. No. 32:9–53).

Submitted by **OSWALDO HERNÁNDEZ-GALLEGOS** (e–mail: oswaldo@ibiologia.unam.mx), **FELIPE RODRÍGUEZ-ROMERO** and **GUSTAVO CASAS-ANDREU**, Instituto de Biología, UNAM, Apdo. Postal 70-153, México, D.F. 04510, México.

SPHENOMORPHUS RUFOCAUDATUS (Red-tailed Groundskink). VIETNAM: VINH PHUC: Tam Dao. June 1985. Vazlav Lanka. Zoologisches Forschungsinstitut und Museum Alexander Koenig, Bonn, Germany (ZFMK 59216). CHINA: HAINAN: Wuzhishan. April 1995. Peter Heimes. Zoologisches Forschungsinstitut und Museum Alexander Koenig, Bonn, Germany (ZFMK 61734). All verified by Wolfgang Böhme. *Sphenomorphus rufocaudatus* was previously only known from its type locality, Gia Lai Province, Tai Nguyen Plateau, Buon Luoi, 60 km N of An Khe, South Vietnam (Darevsky and Nguyen 1983. Zoologicheskii Zhurnal 62:1827–1837). The new finding from Vinh Phuc in northern Vietnam represents the northernmost record of the species both in Vietnam and in general. It extends the known distribution by ca. 900 km air distance to the north. The specimen from Hainan was caught at 700 m elev. and is the first record for China. Besides coloration and pattern, its 60 scales between the second pair of chinshields and the preanal scales are characteristic of *S. rufocaudatus*. Both specimens are males (ZFMK 59216: SVL 42 mm; ZFMK 61734: SVL 49 mm, testes length 5.1 mm). The gastrointestinal tract of the specimen from Vinh Phuc contained remains of about 10 ca. 3.5 mm long bugs (Heteroptera); the specimen from Hainan had eaten one unidentified insect of 15 mm length as well as a cockroach and a grasshopper of 11 mm head–body length each.

Submitted by **ANDREAS SCHMITZ,** Zoologisches Forschungsinstitut und Museum Alexander Koenig, Adenaueralle 160, D-53113 Bonn, Germany (e-mail: A.Schmitz.ZFMK@uni-bonn.de), and **THOMAS ZIEGLER**, Zoologischer Garten Köln, Riehler Str. 173, D-50735 Köln, Germany (e-mail: tziegler@zoo-koeln.de).

STENOCERCUS DUMERILII (NCN). BRAZIL: MARANHÃO: São Pedro da Água Branca Municipality (05°08'S, 48°15'W). 05 May 1998. G. V. Andrade. Museu Paraense Emílio Goeldi, Belém, Pará, Brazil (MPEG 21370). Adult male collected on a branch 1 m above the ground in a secondary forest. Urbano Santos Municipality (ca. 40 m elev.); Fazenda Bacelar (03°12'15"S, 43°09'23"W). 12 March 2003. A. O. Maciel. MPEG 21371. Juvenile specimen captured with pitfall trap in gallery forest. All

verified by T. C. Ávila-Pires. Published distribution (Avila-Pires 1995. Lizards of Brazilian Amazonia [Reptilia: Squamata]. Zoologische Verhandelingen 299, 706 pp.) is restricted to northeastern Pará state, in the northern region of Brazil, between Baía de Marajó in the east, and Gurupi River in the west, and from the coast to ca. 40 km S of Guamá River. These new records for the state of Maranhão extend range ca. 316 km eastward, and ca. 416 km southward. Occurrence of this species in the amazonic secondary forest in São Pedro da Água Branca would be expected, but its presence in the gallery forest in Urbano Santos expands the distribution to the Cerrado domain.

Submitted by **GILDA V. ANDRADE** (e-mail: gandrade@ufma.br), **JUCIVALDO D. LIMA** (e-mail: jucivaldo@yahoo.com), and **ADRIANO O. MACIEL**, Universidade Federal do Maranhão, Departamento de Biologia, Campus do Bacanga, CEP 65080-040, São Luís, Maranhão, Brazil.

URACENTRON AZUREUM WERNERI (NCN). VENEZUELA: AMAZONAS: Quebrada Coromoto, Tobogan de la Selva (05°23'36"N, 67°36'22"W, 120 m elev.). 21 April 1985. P. Lau. Museo de la Estación Biológica de Rancho Grande, Maracay (MEBRG 4157); Santa Barbara, Macuruco (03°54'N, 67°00'W, 100 m elev.). 14 August 2002. A. L. Ulloa. (MEBRG 4213); Isla Tiriquin, Río Guainia (02°16'N, 67°02'W, 120 m elev.). 11 March 1991. E. León. Museo de Historia Natural la Salle, Caracas (MHNLS 11608); Surumoni, near La Esmeralda (03°10'N, 65°40'W, 105 m elev.). July 1998. N. Jerome, G. Schlatte, and N. Ellinger (MHNLS 14097–99, 14106). All verified by G. Rivas. *U. a. werneri* was known from only two localities in Venezuela, one of them the type locality—Alto Orinoco, south of Venezuela—and the other in the Río Mavaca, near Mrakapiwei, Amazonas state (02°10'N, 65°10'W, 130 m elev.) (Avila-Pires 1995. Zool. Verh. Leiden 299:1–706). The record from Quebrada Coromoto extends the known range for the species ca. 440 km N of the closest reported locality (Avila-Pires 1995, *op. cit.*).

Submitted by **CÉSAR MOLINA**, Museo de Historia Natural La Salle, Apartado 1930, Caracas 1010-A, Venezuela (e-mail: washaema@hotmail.com), and **RAMÓN RIVERO**, Ministerio del Ambiente y de los Recursos Naturales, Museo de la Estación Biológica de Rancho Grande, Maracay, Aragua, Venezuela (e-mail: museoebrg@cantv.net).

SERPENTES

BOTHROPS NEUWIEDI DIPORUS (Yarará chica). ARGENTINA: NEUQUÉN: Añelo Department: Fortín de la Piedra, near Neuquén River, 45 km S Añelo. 1 August 2003. Museo de Ciencias Naturales, La Plata (MLP 1797). Verified by J. C. Acosta. First verified province record (Giraudo and Scrocchi 2002. Smithson. Herpetol. Infor. Serv. 132) and southwesternmost record for the species in Argentina. The nearest record for this species is ca. 180 km E in Río Negro Province (Pérez and Avila 2000. Herpetol. Rev. 31:254). Adult specimen (88 mm total length) collected 700 m from Neuquén River in a typical southern Monte habitat. Second *Bothrops* species found in Neuquén province, with *B. ammodytoides* previously reported for this region.

Submitted by **DANIEL R. PEREZ**, Catedra Bioecología, Universidad Nacional del Comahue, Calle Buenos Aires 1400-, Neuquén, CP: 8300, Argentina, **LEOPOLDO R. MARTINEZ**, Painamal 168, B° 11 de Octubre, Centenario, Provincia de Neuquén, CP: 8309, Argentina, and **LUCIANO JAVIER AVILA**, CONICET/Integrative Biology, Brigham Young University, 401 WIDB, Provo, Utah 84602, USA (e-mail: luciano_javier@hotmail.com).

BOTHROPS NEUWIEDI LUTZI (Neuwied's Lancehead). BRAZIL: BAHIA: Camaçari (12°41'51"S, 38°19'27"W). 05 July 1995, Centro de Informações Anti-Veneno da Bahia-CIAVE, Universidade Federal da Bahia-serpentes (UFBA–ser 985); 08 March 1995, UFBA-ser 986. Dias D´Ávila (12°36'45"S, 38°17'49"W). 18 April 2000, CIAVE, UFBA-ser 1191. Verified by M. Trefault. This subspecies is known only in northern Bahia, Brazil where it is found in dry or warm regions of Serra de Monte Santo, Jaguarari and Itiuba (Bahia), and the nearby S. Francisco River, at ca. 300–500 m elev. (Campbell and Lamar 1989. The Venomous Reptiles of Latin America. Cornell Univ. Press, Ithaca, New York). In addition to a range extension of ca. 325 km E (Campbell and Lamar, *op. cit.*), this is the first documented occurrence of *B. neuwiedi lutzi* at sea level.

Submitted by **REJÂNE MARIA LIRA-DA-SILVA, YUKARI FIGUEROA MISE**, Núcleo Regional de Ofiologia e Animais Peçonhentos da Bahia, Departamento de Zoologia, Instituto do Biologia, UFBA, Campus Universitário de Ondina, 40170-210, Salvador, Bahia, Brazil; **GIUSEPPE PUORTO** Instituto Butantan, Av. Vital Brazil, 1500, 05504-900, São Paulo, São Paulo, Brazil, and **VINÍCIUS XAVIER**, Centro Universitário Federal de Alfenas, Rua Gabriel Monteiro da Silva, 714, 37130-000 , Alfenas, Minas Gerais, Brazil.

CONTIA TENUIS (Sharp-tailed Snake). USA: WASHINGTON: Yakima Co: Terrace Heights (T13N R19E S17 and T13N R19E S15). Verified by R. Steven Wagner. Two specimens (CWU 1077–78) were collected on 28 March 2002, one adult and one juvenile. The juvenile was collected inside a utility closet of a nearby residence and the adult was collected near the porch of another. In addition to these specimens, two adults (CWU 1079–80) were found near another residence at the second locality. These were found in the backyard of the home near some small garden stones in July 2002 (precise date not available). The area surrounding these localities is very different from the habitat usually associated with this species. The nearby hillsides are dominated by introduced cheat grass, with some rabbit brush and big sage. The only permanently available water source is a small irrigation canal flowing through the area. However, the yards and gardens of nearby homes could provide suitable microhabitats. Adjacent to these residential collection sites are numerous commercial properties and a small industrial complex. These localities represent new county records for this species and are a 32.5 km range extension S of the nearest confirmed locality in nearby Kittitas County (Storm et. al. 1995. Reptiles of Washington and Oregon. Seattle Audubon Society, Seattle, Washington. 176 pp.). However, given the lack of precise knowledge of this species' distribution in central Washington, it might be found throughout the Yakima River drainage basin.

DIPSAS VARIEGATA (NCN). VENEZUELA: ESTADO BARINAS: Barinitas City, 650 m elev. August 2002. D. Calcaño. Colección de Vertebrados, Universidad de los Andes, Mérida, Venezuela (CVULA 6532). Verified by A. Orellana. First state record, second from the Andean piedmont, 90 km SSW from the closest record from Portuguesa state (Markezich 2002. Herpetol. Rev. 33:71). The species seems to be distributed through all of northern South America and Panama, although the limits are not well defined (Cunha and Nascimento 1993. Bol. Mus. Paraense Emilio Goeldi 9:1–191). In Venezuela it is only known from the Coastal Range (Roze 1966. La Taxonomía y Zoogeografía de los Ofidios de Venezuela. Ediciones de la Biblioteca, Universidad Central de Venezuela, Caracas). The former known distribution and the new record suggest a corridor between the coastal range and the Andean foothills, as has recently been demonstrated for other snakes—*Dipsas latifrontalis* (Manzanilla et al. 2001. Herpetol. Rev. 32:195) and *Stenorhina degenhardti* (Barrio and Calcaño 2001. Herpetol. Rev. 32:280).

Submitted by **DANIEL CALCAÑO,** Serpentarium Los Llanos, Barinitas, Barinas, Venezuela (e–mail: serpentariolosllanos@hotmail.com), and **CESAR L. BARRIO-AMORÓS,** Fundación AndígenA, Apartado Postal 210, Mérida 5101-A, Venezuela (e–mail: cesarlba@yahoo.com).

ELAPHE FLAVOLINEATA (Yellow-striped Ratsnake). WEST MALAYSIA: PAHANG: PULAU TIOMAN: Kampung, Tekek (2°48.942'N, 104°09.289'E). 17 March 2003. Female, SVL 369 mm, TL 468 mm. Perry L. Wood, Timothy M. Youmans, L. Lee Grismer. Verified by Jesse L. Grismer. La Sierra University Photographic Collection 3752. Previously known from Thailand south through west Malaysia and its western islands to Singapore. Also known from Andaman and Nicobar Islands of India and the Indonesia islands of Sumatra, Java, Borneo, Bangka, Billiton and the Indonesian archipelagos of Mergui, Mentawai, and Riau (Schulz 1996. A Monograph of the Colubrid Snakes of the Genus *Elaphe* Fitzinger. Koeltz Scientific Books, Würselen, 439 pp.). This specimen is a new record for Pulau Tioman.

Submitted by **PERRY L. WOOD** (e-mail: perrwood@lasierra.edu), **TIMOTHY M. YOUMANS**, and **THOMAS SZUTZ,** Department of Biology, La Sierra University, Riverside, California 92515–8247, USA.

ELAPHE OBSOLETA (Western Ratsnake). USA: TEXAS: GREGG CO: Near small unnamed creek on private land, ca. 1 km E of Kilgore (32°23'39"N, 94°49'45"W). 20 April 2003. Shelby C. Braman. The University of Texas at Arlington (UTA R–52380). Verified by Ronald L. Gutberlet, Jr. Specimen was a juvenile female (16.7 g, 360 mm SVL, 433 mm total length) collected in a wooden nest box containing Carolina chickadee (*Poecile carolinensis*) nestlings. First county record (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station, Texas. 421 pp.).

Submitted by **SHELBY C. BRAMAN** (shelbycbraman@stemail.uttyl.edu) and **BRIAN E. FONTENOT**, Department of Biology, The University of Texas at Tyler, Tyler, Texas 75799, USA.

ELAPHE SLOWINSKII (= Elaphe guttata guttata in part*)* (Slowinski's Cornsnake). USA: LOUISIANA: CALCASIEU PARISH: State Highway 12, 13.8 km E US Route 190 in Stark, Louisiana (30°23'09"N, 93°32'37"W). 9 May 2003. TCWC 86520. Collected by KJ Lodrigue, Jr., and Ted M. Royer. Verified by Jeff Boundy. New parish record partially fills the distributional hiatus between Jefferson Davis Parish, Louisiana, and known southeast Texas specimens (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana, Louisiana State University Press, Baton Rouge. 300 pp.)

Submitted by **KJ LODRIGUE, JR.**, Texas Parks and Wildlife Department, 10 Parks and Wildlife Drive, Port Arthur, Texas 77640, USA.

HYDROPHIS COGGERI (Cogger's Sea Snake). NEW CALEDONIA: LOYALTY ISLANDS: Lifou: Baie du Santal, 20°46'S, 167°06'E. Observed by Philippe Borsa on 26 January 2002, at 2000 h local time from the research vessel *Alis* of Institut de Recherche pour le Développement (IRD). The bottom was ca. 25 m in depth, and the vessel was anchored with its motor stopped. The snake was captured using a band-net, hauled on the deck, examined, photographed, and released. Total length was ca. 80 cm. Three pictures were taken by J.-L. Justine (Muséum national d'Histoire naturelle, Paris [MNHN]) and P. B. (MNHN Photo collection ine-hydcog 1, ine-hydcog 2, and ine-hydcog 3). Verified by Roger Bour. Also, scales were taken from the tail region using scissors, stored in 90% ethanol, and deposited as tissue sample at Laboratoire Reptiles et Amphibiens, MNHN. First record for Loyalty Islands. This species was previously reported from the waters around New Caledonia's Grande Terre and Chesterfield Reefs (Bauer and Sadlier 2000. The Herpetofauna of New Caledonia. SSAR, Ithaca, New York. 310 pp.; Ineich and Laboute 2002. Sea Snakes of New Caledonia. MNHN and IRD editions, Paris. 302 pp.).

Submitted by **IVAN INEICH**, Muséum national d'Histoire naturelle, Département Ecologie et Gestion de la Biodiversité, FRE 2632 Conservation des espèces, Restauration et suivi des populations, 25 rue Cuvier, F-75005 Paris, France (e-mail: ineich@cimrs1.mnhn.fr), and **PHILIPPE BORSA**, Institut de Recherche pour le Développement, Département des Ressources Vivantes, BPA5, 98848 Nouméa cedex, Nouvelle-Calédonie (e-mail: Philippe.Borsa@noumea.ird.nc).

LIOPHIS TAENIOGASTER (NCN). BRAZIL: PARÁ: Itaituba (4°17'S; 55°59'W), left margin of the Tapajós River, N. Viana, 1996. Linha de Pesquisa em Herpetologia da Amazônia, Faculdades Integradas do Tapajós (LPHA 1321, male, 322 mm). Verified by A. G. Guedes. The species was known from northeastern Brazil from the State of Bahia to Amapá; west through the Amazon Basin to Lomalinda, Colombia, south to Buena Vista, Bolivia, east to the State of Mato Grosso, Brazil (Fernandes et al. 2002. Bol. Mus. Nac., N. S., Zool., Rio de Janeiro [481]:1–14). First record for middle Tapajós River (western Pará), fills the gap between previously known localities. Specimen was collected ca. 234 km airline from Santarém, the nearest previous record (Frota 2001. Herpetol. Rev. 32:123).

Submitted by **JOSSEHAN GALÚCIO DA FROTA** (e-mail: jgfrota@mailbr.com.br) and **ALFREDO PEDROSO DOS**

SANTOS-JR, Laboratório de Herpetologia, Museu de Ciências e Tecnologia da Pontifícia Universidade Católica do Rio Grande do Sul (PUCRS), Av. Ipiranga, 6681, Porto Alegre, RS, Brazil, CEP: 90619-900.

MICRURUS AVERYI (Black-headed Coral Snake). BRAZIL: PARÁ: Instituto de Pesquisa Agropecuária do Norte (IPEAN), Municipality of Belém (01°27'21"S, 48°30'16"W). September–October 1973. L. Carlos. Museu Nacional, Rio de Janeiro, Brazil (MNRJ 7362, juvenile female 399 mm SVL, 40 mm TL). Verified by R. Fernandes. First state report, and easternmost record (Roze 1996. Coral Snakes of the Americas: Biology, Identification, and Venoms. Krieger Publ., Malabar, Florida. 328 pp.); extends known range ca. 1245 km from eastern Manaus, State of Amazonas, Brazil (Vanzolini 1985. Pap. Avuls. Zool., São Paulo 36[8]:77–85), 1000 km from southwestern Suriname (Brongesma 1967. Mem. Inst. Butantan 33[1]:73–79), and 1343 km from northwestern Claudia, State of Mato Grosso, Brazil (Callefo 1997. Herpetol. Rev. 28:210).

Submitted by **PAULO PASSOS,** Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Quinta da Boa Vista s/n, Rio de Janeiro, Rio de Janeiro, 20940-040, Brazil; e–mail: ppassos@mn.ufrj.br.

OPHEODRYS VERNALIS (Smooth Greensnake). USA: VIRGINIA: SHENANDOAH Co: 0.5 km (by road) SE of West Virginia state line on Co. Rd 691; 640 m elev. 25 July 1996. T. Akre. Georgia Museum of Natural History, University of Georgia (GMNH 49215). Verified by Carl H. Ernst. Gravid female found on soil under 0.1 m flat rock on south-facing slope of a rocky, pine-oak woodland frequently disturbed by camping activity. County record. New locality extends known Virginia geographic range northward by ca. 50 km (Mitchell and Reay 1999. Atlas of Amphibians and Reptiles in Virginia. Virginia Department of Game and Inland Fisheries, Spec. Publ. No. 1:v + 122 pp. Richmond, Virginia).

PAREAS VERTEBRALIS (Mountain Snail Snake). MALAYSIA: WEST MALAYSIA: Pahang: Pulau Tioman (02°46.040'N, 104°10.483'E). 21 March 2003. Timothy M. Youmans and Perry L. Wood. La Sierra University Photo Collection (LSUPC–S3696–4000). Verified by Jesse L. Grismer. New island record. Up to the present, *P. vertebralis* is recorded from Bukit Larut, Cameron Highlands and Bukit Fraser of the Malay Peninsula, West Malaysia, and Mt. Kinabalu of Sabah, East Malaysia (Manthey and Grossman 1997. Amphibien und Reptilien Südostasiens. Natur und Tier, Münster. p. 378). This specimen was found at 814 m elev., near the cave Gua Tengkok Air. The snake was climbing on the branch of a rattan palm at night, ca. 2 m above the ground.

PORTHIDIUM LANSBERGII (Landsberg's Hognosed Pitviper). VENEZUELA: ESTADO BOLÍVAR. Municipio Piar, El Retumbo, 7°59'N, 62°44'W. November 2001. A. Bermúdez and J. Manzanilla. Museo de la Estación Biológica de Rancho Grande, Ministerio del Ambiente y de los Recursos Naturales (EBRG 4277); ESTADO DELTA AMACURO, Municipio Casacoima, Los Castillos de Guayana, 8°31'N, 62°23'W. 50 m elev. January 1952. J. R. García. Museo del Instituto de Zoología Agrícola, Universidad Central de Venezuela (MIZA 16-152). Both verified by D. Sánchez. First record for Bolivar and Delta Amacuro states, southernmost known locality for the genus and species in Venezuela and first record from the southern margin of the Orinoco River (Gorzula and Señaris 1998. Scientia Güaianae 8:1–268). Extends known distribution 241 km airline from previous records in the Oriental Region of Venezuela (Roze 1966. Taxonomía y Zoogeografía de los Ofidios de Venezuela. Edición de la Biblioteca, Universidad Central de Venezuela, p. 89; Kornacker 1999. Checklist and Key to the Snakes of Venezuela. PaKo-Verlag, Germany, pp. 176–177).

Submitted by **JESÚS MANZANILLA,** Museo del Instituto de Zoología Agrícola, Facultad de Agronomía, Universidad Central de Venezuela, Aragua, Venezuela (e–mail: manzanillaxxi@hotmail.com), and **MARCO NATERA**, Universidad Rómulo Gallegos, San Juan de Los Morros, Guárico, Venezuela.

PSEUSTES SHROPSHIREI (NCN). VENEZUELA: ESTADO BARINAS: Barinitas City, sector El Cacao, 600 m elev. 14 May 2003. D. Calcaño. Colección de Vertebrados, Universidad de los Andes, Facultad de Ciencias, Mérida (CVULA 6533). First state record, 300 km SW of Valencia, the closest locality east of the Andes (Rivas and Molina 1998. Herpetol. Rev. 29:178). ESTADO TÁCHIRA: La Trampita, between Pregonero and Fundación, Uribante Dam. 7 October 1985. Proyecto Faunístico Uribante-Caparo (CVULA 4575). La Trampita, between Pregonero and Fundación, Uribante Dam. July 1986. Proyecto Faunístico Uribante-Caparo (CVULA 4745). Recently reported by Rivas and Molina (1996. Resúmenes del IV Congreso Latinoamericano de Herpetologia, Santiago de Chile: 292) from Táchira state but at the western side of the Andes or Maracaibo Lake basin, but only 50 km airline through the Andes. Rivas and Molina (*op. cit.*) also reported the species from central and western Venezuela. The two Táchira records are the first from the eastern slopes of the Andes. The species is distributed from Costa Rica to Ecuador west of the Andes (Peters and Orejas-Miranda 1986. Catalogue of Neotropical Squamata, Part I. Snakes. Smiths. Inst. Press. Washington, D.C.), reaching western Venezuela at its eastern limit, very much like the

recently reported toad *Bufo haematiticus* (Barrio 2001. Herpetol. Rev. 32:189). This is another northern species, known from the "región orocostense" and "región del lago de Maracaibo" (Barrio-Amorós 1998. Acta Biol. Venezuelica 18:1–93), that supports the hypothesis that the eastern Andean piedmont acts as a corridor for some northern species, e.g., *Stenorhina degenhardti* (Barrio and Calcaño 2001. Herpetol. Rev. 32:280) and *Dipsas latifrontalis* (Manzanilla et al. 2001. Herpetol. Rev. 32:195).

Submitted by **DANIEL CALCAÑO,** Serpentarium Los Llanos, Barinitas, Barinas, Venezuela (e-mail: serpentariolosllanos@hotmail.com), and **CESAR L. BARRIO-AMORÓS,** Fundación AndígenA, Apartado Postal 210, Mérida 5101-A, Venezuela (e–mail: cesarlba@yahoo.com).

RHADINAEA FLAVILATA (Pine Woods Littersnake). USA: FLORIDA: Brevard Co: Melbourne, Royal Poinciana Boulevard, 1.4 km E of Brevard Co. Rd. 509 (Wickham Rd.), on screened porch of residence in Lansing Ridge subdivision, across street from disturbed marsh and artificial pond, on land formerly a transition area between sand pine ridge and slash pine/scrub. 24 August 1993. Richard L. Turner. Verified by David L. Auth. Florida Museum of Natural History, University of Florida (UF 89309). New county record (Ashton and Ashton 1988, Handbook of Reptiles and Amphibians of Florida. Part 1. The Snakes. Second ed. Windward Publ., Miami, 176 pp.). This is the first new county record for *R. flavilata* along the Atlantic Coast of Florida since Ashton and Ashton (1988). Gottlieb's (1984, Herpetol. Rev. 15:21) earlier record for Palm Beach Co. on the Atlantic coast of Florida was overlooked by Ashton and Ashton (1988) and by Reichling and Louton (1989, Herpetol. Rev. 20:76).

Continuing fieldwork in the Mosquitia of Honduras has demonstrated the presence of three species of snakes hitherto unknown from the country. In recent years, this lowland region in the eastern portion of the country has produced a number of additions to the known snake fauna of Honduras (McCranie et al. 2001; Wilson et al. 2003).

A recent update of the reptile fauna of Honduras (Wilson and McCranie 2002) listed 113 species of snakes from the country. Wilson et al. (2003) reported an additional two species, bringing the total to 115 species. The three species reported in this paper increase the total to 118 species. This figure is only 15 species fewer than the number (133) reported by Savage (2002) from Costa Rica, well known for its speciose herpetofauna.

Specimens of the three species reported below came as a result of fieldwork we conducted in the eastern portion of the Mosquitia during May and June of 2003. As in the year 2002 (Wilson et al. 2003), we surveyed three proposed or recognized protected areas, i.e., the Río Kruta Biological Reserve, the Rus Rus Biological Reserve, and the Tawahka-Asangni Biosphere Reserve. We worked in the area of the Tawahka-Asangni Biosphere Reserve adjacent to the Río Coco from 16–21 May at localities along one of its tributaries, the Caño Awalwás. Our campsite and areas in which we collected still remain in essentially pristine lowland broadleaf rainforest, although recent illegal deforestation is now evident at the mouth of Caño Awalwás and in adjacent areas along the Río Coco, and is expected to spread inward to the area of our work in the not too distant future, i.e., into an area recognized as a protected area of global significance, both from a biological and a cultural perspective. From 26 May to 2 June, we collected in the vicinity of a locality, also in essentially undisturbed lowland broadleaf rainforest in the proposed Rus Rus Biological Reserve known as Bodega de Río Tapalwás, a hunting camp along the Río Tapalwás, a tributary of the Río Rus Rus. Finally, we surveyed localities along the Río Kruta, located within the proposed Río Kruta Biological Reserve, from 8–14 June, collecting in fresh water marshes and disturbed lowland broadleaf swamp forest. All localities are within the department of Gracias a Dios.

The colors in life reported below follow the colors (capitalized) and codes (in parentheses) of Smithe (1975–1981). All specimens

are deposited in the Florida Museum of Natural History at the University of Florida (UF).

Enuliophis sclateri (Boulenger)

Two specimens of this snake were collected. One is a female (UF 137175) collected on 20 May 2003 at 100 m elevation in leaf litter at Caño Awalwás. The other is a male (UF 137177) found on 1 June 2003 at 190 m elevation in leaf litter at Bodega de Río Tapalwás. Both specimens were active at night. Color in life of UF 137175 was as follows: dorsum Blackish Neutral Gray (82) to second dorsal scale row; first dorsal scale row and venter Pale Neutral Gray (86); underside of tail Pale Neutral Gray with brownish gray smudges scattered along midline; dorsum of head Blackish Neutral Gray from tip of snout to level of posterior edge of supraoculars; side of head Blackish Neutral Gray above supralabials to posterior edge of eye, rest of head and first three and one-half dorsal scales posterior to parietals ivory white; chin same color as rest of venter; iris black. The coloration of the other specimen is essentially the same as that described for UF 137175. Both of these specimens are of the dark-headed type, as described by Savage (2002). The scutellational data on these two specimens are consistent with those reported for the species by McCranie and Villa (1993), except that UF 137177 has 6-6 supralabials (an error in the number of infralabials for this species occurs in Savage 2002). These specimens represent range extensions of approximately 230 km NNE and 265 km NE, respectively, from the nearest locality in Nicaragua (Matagalpa, Depto. Matagalpa; Köhler 2001).

Sibon annulatus (Günther)

A single male specimen of this snake (UF 137178) was collected while active at night in the top of a small tree in slightly disturbed broadleaf swamp forest on the outskirts of Swabila at 5 m elevation along the Río Kruta on 10 June 2003. Color in life of UF 137178 was as follows: dorsum with 28 Sepia (119)-edged Walnut Brown (221B) crossbands on body and 17 on tail, Sepia edging of bands coalesces ventrally and extends onto venter to join or alternate with ventral extension on other side; interspaces Flesh Ocher (132D) middorsally grading to Grayish Horn Color (91) laterally, in turn grading to white on lowermost dorsal scale rows; venter white except for Sepia crossbands; head Burnt Sienna (132) above with Sepia blotching; lateral portion variegated with Burnt Sienna, Sepia, and white; chin white with Sepia blotching; iris grayish brown. UF 137178 has a single preocular on either side of the head, a condition heretofore unreported for this species (Savage 2002), which usually has no preoculars. The other scutellational data are consistent with those given by Savage (2002). This specimen represents a range extension of approximately 225 km NE of the nearest locality in Nicaragua (Reserva Biosfera Bosawas, Depto. Jinotega; Köhler 2001). Savage (2002:630) stated that the distribution of this snake extended to "the Atlantic versant of eastern Honduras." However, UF 137178 is the first specimen collected in Honduras.

Urotheca decipiens (Günther)

A single female specimen of this snake (UF 137176) was collected at the edge of our camp at dusk at 190 m elevation along the Río Tapalwás at Bodega on 29 May 2003. Color in life of UF 137176 was as follows: middorsum Sepia (219), lateral portion of dorsum Hair Brown (119A), two areas separated by narrow Straw Yellow (56) stripe on middle of scale row 5, lateral area of dorsum bounded below by zigzag white stripe on adjacent portions of rows 1 and 2; ventrolateral area Hair Brown (lower portion of row 1) confluent with similarly-colored blotch on lateral edge of ventrals; remainder of venter white; dorsum of head Burnt Sienna (132) to mid-parietal level, followed by Chrome Orange (16) nuchal band extending two scales posterior to parietals; supralabials pinkish white, bounded above by dark brown line; lateral and ventrolateral stripes continue to end of tail; iris brown. The ventral count for this specimen is 143, which is three scales higher than the high end of the range (122–140) reported by Myers (1974) and repeated by Savage (2002). The locality of this specimen represents a range extension of approximately 470 km N of the nearest locality in Costa Rica, which appears to be the La Selva region in Heredia Prov. (Savage 2002, supplied no locality data to support his distribution maps).

Acknowledgments.—We thank F. Wayne King, Max A. Nickerson, Fred G. Thompson, and the Reptile and Amphibian Conservation Corps (RACC) for granting funds to support our field work. Collecting and export permits were issued by Conrado González and Martha Moreno of COHDEFOR, Tegucigalpa. Valuable assistance with securing these permits was provided by Mario R. Espinal. Ruben Castro Lobo (COHDEFOR) and Siyyid Aly Romero (PROBAB) of Puerto Lempira were helpful in providing transportation and logistical support. We were assisted in the field by Tomás Manzanares Ruís, John Slapcinsky, Froylán Llezett, Luís Lacuth, Volven Graham R., and Antonio D. Coello.

Alpine, Texas 79830, USA

The gray-banded kingsnake, *Lampropeltis alterna*, is a medium-sized colubrid endemic to the Chihuahuan Desert regions of western Texas and southeastern New Mexico in the United States. Based on preserved museum specimens, *L. alterna* have been documented from ten counties in Texas (Werler and Dixon 2000). Numerous gaps exist between documented populations. Specimens have been collected from these gaps and maintained in captive collections for years but few were deposited in museum collections. Herein we report on several cataloged museum specimens that document new county records and fill in gaps between previously documented populations. Specimens verified by Jonathan A. Campbell (UTACV), James Mueller (SRSU), and Kenneth Wray (UF).

New Distributional Records for Amphibians and Reptiles from Quintana Roo on the Yucatán Peninsula, México

J. ROGELIO CEDEÑO-VÁZQUEZ
RENÉ CALDERÓN
and
CARMEN POZO
El Colegio de la Frontera Sur, Unidad Chetumal
Apdo. postal 424, 77000 Chetumal, Quintana Roo, México
e-mail: rogeliocv@mexico.com

During the course of fieldwork from 1992 through 2000 in Quintana Roo, México, several amphibians and reptiles were found that represent either distributional range extensions on the Yucatán Peninsula, or new state records for Quintana Roo. All records are from the Municipality of Othón P. Blanco in the southern portion of the state, unless indicated otherwise. The authors collected all specimens, except for those identified in the text. This account reports a range extension for one amphibian, and six state records and 16 range extensions for reptiles. All voucher specimens are deposited in the Herpetological Collection of the Museo de Zoología, El Colegio de la Frontera Sur, Unidad Chetumal, Quintana Roo (ECO-CH-H). Oscar Flores-Villela verified all specimens, except *Ctenosaura alfredschmidti*, which was verified by Gunther Köhler. Former distributional records, except for *C. alfredschmidti*, are based on Lee (1996).

New State Records

Claudius angustatus (Narrowbridge Musk Turtle). La Unión (17°53'47"N, 88°52'34"W). 01 July 1993. Máximo Suárez Salas. ECO-CH-H 0341. This new state record closes the gap between previously known localities in southeastern Campeche and northeastern Belize.

Ctenosaura alfredschmidti (Alfredschmidt's Spinytail Iguana). Municipality of Felipe Carrillo Puerto, Dzulá village (19°36'09"N,

88°24'56"W). 15 May 1999. Carlos Gracida. ECO-CH-H 1321. An adult female captured in secondary tropical forest. This locality extends the range of the species about 215 km from the type locality at Pablo Garcia, Campeche (Köhler 2000), and represents the northeasternmost record on the Yucatán Peninsula.

Norops pentaprion (Lichen Anole). Chetumal (18°29'57"N, 88°18'57"W). 19 September 1999. ECO-CH-H 1437-1618. A new state record that extends the range of the species ca. 200 km NE of the closest known localities in Belize and Guatemala.

Celestus rozellae (Rozella's Lesser Galliwasp). 15 km SE Tres Garantías, Campamento la Pirámide (18°10'N, 88°52'W). 13 October 1999. Luis Antonio Mora and Roger Braga. ECO-CH-H 1634. New state record and a range extension of about 170 km N of the nearest records in Belize and Guatemala.

Ramphotyphlops braminus (Braminy Blind Snake). Chetumal (18°31'05"N, 88°19'36"W). 12 April 1998, 14 June 1999. ECO-CH-H 0530, 1429. These are the first records for this species on the Yucatán Peninsula. The specimens were both found in separate backyards within the city.

Tantillita lintoni (Linton's Dwarf Short-Tailed Snake). Chetumal (18°29'57"N, 88°18'57"W). 06 August 1998. ECO-CH-H 1120. A new state record that extends the range ca. 225 km NE from the closest locality in Guatemala.

Range Extensions

Physalaemus pustulosus (Tungara Frog). Km. 7, Carretera a San José de la Montaña (18°24'45"N, 89°00'25"W). 28 September 1999. Luis A. Mora. ECO-CH-H 1468. Extends the range ca. 65 km SW from the only previous state record.

Sphaerodactylus glaucus (Dwarf Gecko). Bahía de Chetumal, Punta Mainada (18°23'21"N, 87°55'07"W). 4 September 1998. ECO-CH-H 1138. First record for southeastern Quintana Roo, and extends the range ca. 50 km E from the nearest record.

Hemidactylus frenatus (Common House Gecko). Chetumal (18°29'57"N, 88°18'57"W). 18 February 1998. ECO-CH-H 0902-0903. These specimens represent the southernmost records for Quintana Roo, and extend the range 250 km S from the closest record. This species is very common in Chetumal and surrounding areas.

Corytophanes cristatus (Smooth-headed Helmeted Basilisk). 8 km N La Unión (17°56'57"N, 88°52'13"W). 7 April 1993. Humberto Bahena-Basave. ECO-CH-H 0277. This record extends the range ca. 100 km N from the closest record in Belize.

Corytophanes hernandezii (Hernandez's Helmeted Basilisk). 8 km N La Unión (17°56'57"N, 88°52'13"W). 7 April 1993. Humberto Bahena-Basave. ECO-CH-H 0278. This record extends the range of this species ca. 100 km N from the closest record in Belize.

Iguana iguana (Green Iguana). La Unión (17°53'47"N, 88°52'34"W). 24–25 November 1992. Humberto Bahena-Basave. ECO-CH-H 0169–0170. First mainland records for Quintana Roo, as the previous state records were from Cozumel Island. These specimens extend slightly the range northward from the closest records in northern Belize.

Sceloporus lundelli (Lundell's Spiny Lizard). Bahía de Chetumal (18°48'13"N, 88°06'31"W). 2 September 1998. ECO-CH-H 1135–1136. This record extends the range 250 km southward from the only previous state record and closes the reported gap between the northern and southern populations on the Yucatán Peninsula.

Sphenomorphus cherriei (Brown Forest Skink). San Felipe Bacalar (18°42'N, 88°23'W). 6 May 2000. Pedro Mis. ECO-CH-H 1648. Extends the range ca. 100 km NE from the closest record in northern Belize.

Masticophis mentovarius (Neotropical Whipsnake). La Unión (17°53'47"N, 88°52'34"W). 23 June 1993. Humberto Bahena-Basave. ECO-CH-H 0333. This is the first record for southern Quintana Roo and a 30 km range extension from the nearest locality in Belize.

Scaphiodontophis annulatus (Guatemalan Neckband Snake). Kohunlich Archaeological Site (18°25'50"N, 88°48'45"W). 16 June 1994. ECO-CH-H 0483. 15 km NW Bacalar, Ejido La Laguna (18°42'N, 88°23'W). 18 July 2000. J. Enrique Escobedo Cabrera. ECO-CH-H 1649. Extends the range ca. 100 km N from the closest record in Belize and closes the distributional gap between the northern and southern populations on the Yucatán Peninsula.

Symphimus mayae (Yucatan White-lipped Snake). Chetumal (18°29'57"N, 88°18'57"W). 07 August 1998. ECO-CH-H 1121. This record closes the distributional gap on the Yucatán Peninsula between the northern populations in México and southern populations in Belize.

Thamnophis marcianus (Checkered Garter Snake). 4.5 km S San Pedro Peralta (18°42'N, 88°53'W). 24 August 1994. J. Enrique Escobedo Cabrera. ECO-CH-H 0416. This is another isolated record for this species on the Yucatán Peninsula, and the first from southern Quintana Roo.

Urotheca elapoides (False Coral Snake). Kohunlich Archaeological Site (18°25'50"N, 88°48'45"W). 12 June 1994. ECO-CH-H 0482. This is the only known record in southern Quintana Roo and extends the range ca. 150 km N from closest localities in Belize, and closes the distributional gap between northern and southern Yucatán Peninsula populations.

Xenodon rabdocephalus (False Fer-De-Lance). Kohunlich Archaeological Site (18°25'06"N, 88°47'54"W). 18 June 1994. ECO-CH-H 0485. This is the only known record for southern Quintana Roo and confirms the range proposed by Lee (1996) for the eastern portion of the Yucatán Peninsula.

Typhlops microstomus (Yucatecan Blind Snake). Chetumal (18°29'57"N, 88°18'57"W). 7 September 2000. ECO-CH-H 1652. This is the only known record for southern Quintana Roo and extends the range by ca. 100 km N from the closest record in Belize.

Agkistrodon bilineatus (Cantil). Chetumal (18°29'57"N, 88°18'57"W). 21 September 1993. J. Enrique Escobedo Cabrera. ECO-CH-H 0418. Cocoyol (18°09'53"N, 88°41'28"W). 12 April 1997. Photographic Collection, ECO-CH-H, R 0016. These are the only known records for southern Quintana Roo and extend the range by ca. 50 km N and 20 km W from the nearest records in northern Belize.

Acknowledgments.—We are indebted to Oscar Flores for verifying specimens and encouraging us to publish these distributional accounts. We also thank the collectors and the staff of the Museum of Zoology from El Colegio de la Frontera Sur, Unidad Chetumal for helping with fieldwork. We are also grateful to Sophie Calmé for reviewing the manuscript.

The Indianapolis International Airport (IIA) is located near the southwestern edge of Indianapolis, Indiana, USA. South and west of IIA is a series of properties purchased by IIA as part of a noise reduction plan, and to preserve habitat for the federally endangered Indiana bat (*Myotis sodalis*). These properties consist of many small, fragmented residential areas and woodlands surrounded by a matrix of agriculture and industry (Sparks et al. 1998; Foster et al., *ms. submitted*). The properties extend south from U.S. 40 to U.S. 67 along the East Fork of White Lick Creek, and westward from IIA to Indiana 267 (IN-267). Interstate 70 (I-70) bisects the study site from east to west, and many smaller roads dissect the interior of the study area. Permanent water is available in the form of a perennial stream (East Fork of White Lick Creek), many recently constructed retaining ponds (concentrated in a warehouse district N of I-70), farm ponds, and a wetland complex developed to mitigate for wetlands lost during IIA expansion.

Hendricks County is one of the least studied counties in Indiana with only 15 species of reptiles and amphibians having been previously documented (Minton 2001). The absence of even baseline information about the herpetofauna of the area limits the ability of land managers to protect those species that are present. In this paper we report 10 new county records encountered while surveying the herpetofauna of the IIA properties, while a sister paper describes the overall amphibian and reptile community (Foster et al., *ms. submitted*). Voucher specimens were deposited in the Indiana State University Vertebrate Collection (ISUVC). Identifications were verified by J. O. Whitaker, Jr., Professor of Life Sciences and director of ISUVC.

Anura

Bufo americanus (American Toad). 4 km S, 1.2 km E of jct of I-70 and IN–267 (ISUVC 3594). 8 August 2000. Captured in mitigation wetlands.

Hyla chrysoscelis (Cope's Gray Treefrog). 3.12 km S, 1.5 km E of jct of I-70 and IN–267 (ISUVC 4019). 7 June 2001. Identification was verified by call prior to collection. Captured in mitigation wetlands.

Pseudacris crucifer (Spring Peeper). 3.12 km S, 1.5 km E of jct of I-70 and IN-267 (ISUVC 4021). 7 June 2001. Captured in mitigation wetlands.

Pseudacris triseriata (Western Chorus Frog). 2.9 km N, 3.7 km E of jct of I-70 and IN-267 (ISUVC 4022). 9 July 2001. Captured while calling in a roadside ditch.

Testudines

Apalone spinifera (Spiny Softshell). 0.75 km N, 3.25 km E of jct of I-70 and IN-267 (ISUVC 4108). 18 July 2002. Taken while swimming in the East Fork of White Lick Creek.

Chrysemys picta (Painted Turtle). 0.74 km S, 1.08 km E of jct of I-70 and IN-267 (ISUVC 4035). 26 April 2001. Found dead beside a farm pond.

Terrapene carolina (Eastern Box Turtle). 0.75 km S, 1.25 km E of jct of I-70 and IN-267 (ISUVC 4107). 23 May 2001. Found dead on county road 800S.

Trachemys scripta (Red-eared Slider). 3.12 km S, 1.5 km E of jct of I-70 and IN-267 (ISUVC 4033). 30 May 2001. Found dead along the edge of mitigation wetlands.

Serpentes

Thamnophis sirtalis (Eastern Garter Snake). 0.48 km S, 2.54 E of jct of I–70 and IN–267 (ISUVC 3596). 30 July 1998. Captured beneath debris.

Elaphe obsoleta (Black Rat Snake). 1.25 km S, 0.75 km E of jct of I–70 and IN–267 (ISUVC 4105). 4 June 2002. Found dead on county road 750S.

Acknowledgments.—B. L. Everson, C. L. Gummer, S. S. Nard, J. J. Sheets, and R. G. Wickens provided assistance in the field as did C. M. Ritzi and J. O. Whitaker, Jr. who also provided assistance with the manuscript. Partial funding and logistical support was provided by the Indianapolis Airport Authority, the Indiana Academy of Science, and the Department of Life Sciences at Indiana State University.

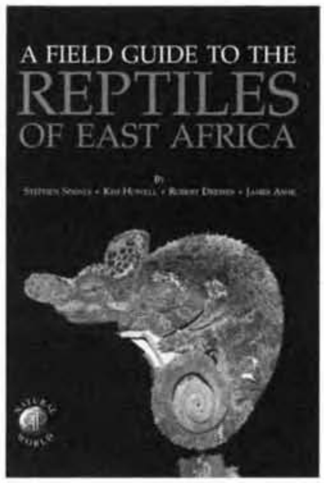
e-mail: bitis@telkomsa.net



This book (abbreviated here to *FGEA*) covers all East African reptiles in the countries of Kenya, Uganda, Tanzania, Burundi, and Rwanda. It is a collaborative effort among six herpetologists, each with many years of field experience in East Africa.

It is a thick book, measuring 250 x 180 x 35mm, so it is unwieldy as a field guide. In fact it is not really a field guide at all, containing much more information than is relevant for field identification. The first 32 pages are devoted to the Preface, Sources and Acknowledgements, Further Reading on East African Reptiles, and several introductory essays, including an illuminating one on The Zoogeography of the East African Reptile Fauna, and others on Reptiles in the East African Environment, Observing and Collecting Reptiles, Reptile Conservation—The Role of National Parks and Museums, Identifying Reptiles, Common Names, Photographing Reptiles, Notes on the Husbandry of East African Reptiles, and What are Reptiles? A similar generous series of appendices occur at the back, including Reptile Biology Illustrations (19 pictures in 3+ pp.), Habitats (3 pp.), Notes on Snakebite (8 pp.), Local Names in Swahili and 20 tribal languages (3+ pp.), a comprehensive and very useful Gazetteer with full co-ordinates (12+ pp.), Glossary (6 pp.), and References (1 p.).

As pleased as I am as a curator to get such a useful gazetteer I am not sure it and all the other pages allocated to these topics repay the space. Especially as the *FGEA* is pushing the upper limit of a field companion. A leaner book would help reduce the price and thus make it more affordable in Africa and I would certainly encourage plans to produce an additional thinner true field guide.

The Species Accounts are divided into five sections covering: 1. Chelonians (pp. 34–65); 2. Lizards (pp. 66–255); 3. Worm Lizards (pp. 256–266); 4. Crocodiles (pp. 268–277) and 5. Snakes (pp. 278–496), with keys to families, genera and species. Each species account provides the available information on Identification, Habitat and Distribution, Natural History, and Venom (where relevant for snakes). Most are illustrated with color photographs taken by numerous contributors, but the majority are by Stephen Spawls. A small distribution map gives the range of each species in East Africa. The apparently disjunct populations of many species probably reflect poor collecting in the intervening areas.

The quality of the photography is generally good, with individual pictures ranging from excellent to poor. The latter include many of the pickled museum rarities, which might have been better illustrated by simple drawings showing diagnostic features and reference to pictures of commoner species of similar habitus. The series of color photographs of representative habitats I would have preferred in the front section, and many of the reptile biology illustrations should have been excluded, particularly the shots of the "snake man free-handling" boomslang and black mamba. They serve no useful purpose and send the wrong message that simply perpetuates the "Crocodile Dundee" stereotype that blights so many of today's TV reptile 'documentaries.'

I have to congratulate the Natural History section of Academic Press for the quality of the *FGEA*. As an author I envy the use of glossy paper throughout that allows the presence of color on nearly every page, the surfeit of color photographs, and the hardcover! It is a far-sighted publisher that invests so much in what many others seem to consider a speciality market. Having said that, however, the *FGEA* contains too many silly editorial mistakes and also shows evidence of confused layout, presumably resulting from its multi-authored nature and from what appear to be last-minute amendments to the book.

An example of the latter is the confused treatment of the Eublepharidae. This family has been distinguished from true geckos for some time (e.g., Grismer 1988), but it is not included in the total of lizard families found in East Africa (p. 70). A brief description of the family and its only East Africa representative (*Holodactylus africanus*), however, is included between the accounts for *Ebenavia* and *Stenodactylus*, i.e. in the middle of the Gekkonidae. Because of this last minute update the second couplet in the key to lizard families in East Africa (p. 71; "2a: Eyelids absent, eye cannot close. Geckoes, Gekkonidae. p.72") is almost immediately contradicted in the first couplet in the key to East African gecko genera (p. 73; "1a. Eyelids present, moveable. *Holodactylus africanus*"). The authors may well debate the status of the family Eublepharidae (although this has received subsequent support; e.g., Ota et al. 1999; Kratochvíl and Frynta 2002), but the current treatment in the *FGEA* is hybrid and confusing.

Editorial overview is also poor with respect to standard fonts for headings (e.g. *Family* GEKKONIDAE, p. 72), scientific names not in italics (e.g., A. vauereselli, p. 170), and generic names without leading capital (e.g., *elapsoidea*, p. 447). The Natal Province in South Africa, mentioned in the text, has been renamed KwaZulu-Natal for nearly 10 years.

The layout of Family and Suprafamily headings is also inconsistent. Higher order relationships of reptile families are rarely discussed, which is fair enough given ongoing conflict over the various hypotheses that have been proposed. However, within the snake section there is an orphan heading 'Infraorder Scolecophidia' (p. 280) without subsequent headings heralding the lineages Henophidia or Cenophidia. Although subfamily headings are used within the Boidae, these are not used for the Causinae within the Viperidae, even though the subfamily is recognized in the

introductory section to the family.

In his review, Broadley (2002) has given an extensive Corrigenda and Addenda that should be consulted for many oversights and omissions, as well as a number of misidentified photographs. These will not be repeated below, but a number of additional corrections are noted. Although the familial and generic relationships of many African snakes remain problematic, a number of reassignments have been made in the literature. Acceptance of some of these changes remain controversial (e.g., recognition of *Python natalensis* as a full species, proposed by Broadley 1999, but not adopted by others, e.g., Joger and Lambert 2002; generic splitting of African *Coluber* (e.g., Schätti and Utiger 2001), and species boundaries in *Echis*, see below). Treatment of many of these changes in the *FGEA* is inconsistent; some changes have been adopted (e.g., *Buhoma* for African '*Geodipsas*', Ziegler et al. 1997; incorporation of *Gastropyxis* into *Hapsidophrys*, p. 363), whereas others have not. In the latter case it is not obvious whether the authors reject these changes or have overlooked them.

Feylinia contains six not three species and the population from Pointe Noire, Uganda, displays morphological variation that might merit further study (Brygoo and Roux-Estève 1983). The reduced eyes of these fossorial skinks are also best described as degenerate not "primitive." *Feylinia currori* remains the only species occurring in East Africa, but midbody scale counts range from only 22 to 28.

Thankfully the authors have not followed Klaver and Böhme (1986, 1997) in referring a number of East African chameleons to *Bradypodion*. This problematic transfer has not received much favor in Africa (e.g., Branch 1998) or subsequent morphological (Bauer 1997) or genetic support (Townsend and Larson 2002; Tolley et al. 2003). Despite this, new taxa such as a subspecies of *C. tavetanus* from the Taita Hills, Kenya, continue to be assigned to *Bradypodion* (Lutzmann and Neças 2002).

Many issues regard snakes. Sand boas of the genus *Eryx* have been revised, with the revival of *Gongylophis* for *G. colubrinus* (Tokar 1996). The Spotted Cape Wolf Snake (*Lycophidion capense vermiculatum*, p. 323) was placed in synonymy of typical *L. capense* by Broadley (1996). The illustration of *Hormonotus modestus* (p. 329) is not this species, but probably the Forest File Snake, *Mehelya poensis*. Tongue-in-cheek, I note that the authors seem still to be troubled by the class-struggle—why else the confusion of Ruspoli's Shovel-snout (p. 347) and Prince Ruspoli's Shovel-snout on the very next line!

Generic assignment and species boundaries in Old World *Coluber* sensu lato remain problematic. Blanket assignment of African *Coluber* to *Hemorrhois* (Welch 1983), or for some species (e.g., *algirus* and *dorri*, Chippaux 2001) is premature (Schätti and Utiger 2001; Pauwels and Branch 2003). Although it has long been known that *Coluber* sensu lato is unwieldy, its partitioning into monophyletic units has been problematic (e.g., Schätti 1986, 1987) and most authors (e.g., Largen and Rasmussen 1993 and *FGEA*) have continued to use *Coluber*, whilst others show the proposed reassignments in brackets, although not as explicit subgenera (e.g., Baker et al. 2002). Recently Schätti and Utiger (2001) have partitioned *Coluber* into a number of genera, although at least nine Old World racers remain unassigned (and best treated as *Coluber* sensu lato). The taxonomic status of *Coluber smithi* (not *smithii* as in the *FGEA*) is particularly confused. The *FGEA* notes that it was revived as a full species from *C. florulentus* (Schätti 1988), however, it was subsequently treated as a subspecies of *C. brevis* by Lanza (1988). Along with a number of other Old World racers (e.g. *florulentus, largeni, taylori*, etc.), and on the basis of morphological and molecular analysis, *brevis* (including *smithi*) has been transferred to the genus *Platyceps* (Schätti and Utiger 2001).

The illustration of *Hemirhagerrhis nototaenia* from Watamu (p. 394) is of the newly revived *H. hildebrandtii* (Broadley and Hughes 2000), which in Kenya is known only from Mombasa. The species is rupicolous and appears more closely related to *H. viperina* of northern Namibia, and might represent another example of vicariance associated with the proposed arid corridor postulated to have connected southwest and northeast Africa (Balinsky 1962). The gender of the sea snake genus *Pelamis* Daudin 1803 (Hydrophiidae) is feminine, and the correct name for the yellow-bellied seasnake becomes *Pelamis platura* (Lanza and Boscherini 2000).

Saw-scaled vipers (*Echis*) are an important medical risk in the northern scrublands of Africa, so it is important that their underlying taxonomy be resolved. This is complicated by regional variation and patchy material, and two recent controversial papers (Cherlin 1990a, 1990b) have proposed numerous changes to our understanding of African and Near East *Echis*, including the description of new species. A number of recent taxonomic (Golay et al. 1993) and geographic (Largen and Rasmussen 1993) checklists have grappled with these problems and have presented different interpretations. The taxonomic status of populations in northern Kenya is thus difficult, and the treatment in the *FGEA* reflects this. Two populations have been named in northern Kenya, *aliaborri* from the Wajir region, and *leakeyi* from northwest Kenya. Although both were initially described as races of *E. carinatus*, the *FGEA* follows Golay et al. (1993) and treats both as races of *E. pyramidium*. However, taxonomic conflict remains and Largen and Rasmussen (1993) treat both as races of different species (*E. varius* and *E. pyramidium*, respectively). Initially, the *FGEA* illustrated both as *E. carinatus aliaborri* and *E. c. leakeyi*, although this has been corrected in subsequent reprints.

The taxonomy of many African groups is being drastically revised, following more extensive surveys and the application of molecular studies. A number of important papers that affect the taxonomy of a number of species have appeared subsequent to the guide's publication. I discuss these only to aid the interested reader, and to highlight where additions and corrections will be needed in future editions of the guide.

Another new dwarf forest chameleon (*Rhampholeon moyeri*) has been described from the Udzungwa Mountains, Tanzania (Menegon et al. 2002). In a study that has wide implications, *Mabuya* is now restricted to the Neotropical radiation (Mausfeld et al. 2002). *Trachylepis* has been shown to be the earliest available name for the African radiation of "*Mabuya*" (Bauer 2003), albeit that the status of some species, e.g., *ivensi*, may require further assessment. Broadley (2001) revised the genus *Thelotornis*, describing a new species (*T. usambaricus* from Tanzania) and treated *T. mossambicanus* as a valid species (to which the illustration on p. 391 is referable). Subsequently, Broadley and Wallach (2002) revised the Dispholidini, describing a new genus and species (*Xyelodontophis uluguruensis*) from the Uluguru Mountains, Tanzania. They also considered *Thrasops schmidti* as

a valid species, restricted to the forests of the Kenya highlands from Mount Kenya south to Nairobi. No races of *Rhamnophis aethiopissa* or *Dispholidus typus* are now recognized. Rasmussen (2002) reviewed the genus *Micrelaps,* validating *M. bicoloratus* as a full species, relegating *M. boettgeri* to a junior synonym of northern *M. vallanti,* and describing a new subspecies, *M. bicoloratus moyeri*, from Tanzania. The distribution of *Naja pallida* no longer occurs into northern Sudan or Egypt, where it is replaced by the newly-described *Naja nubiae* (Wüster and Broadley 2003).

Finally I should stress that reviews are always personal assessments and I fully acknowledge that many of my comments might be individual idiosyncrasies. The mistakes I have noted, like those outlined by Broadley (2002), are made to assist the many people who have purchased or will buy the *FGEA*. Good field work requires dependable equipment and field guides, like good hiking boots, are indispensable. Both usually need a period in which they are broken-in and later, as they become scuffed and show signs of age, need constant care and upkeep. But the good ones soon come into their own and become trusted companions. The *FGEA* is well on its way to such a status. But these are early days and it requires a bit of a polish (as do all field guides). For anyone wanting to identify or understand the biology of East African reptiles the *FGEA* is *the* book to have, and I congratulate all the authors.

aaron.bauer@villanova.edu

Although many publications are available on the herpetofauna of the West Indies in general (e.g., Schwartz and Henderson 1991) and on that of the Greater Antilles in particular, the Lesser Antilles have not been treated in such detail. Malhotra and Thorpe (1999) considered the region as a whole, providing short accounts of each island group, and the amphibians and reptiles of Anguilla have recently been the focus of a small book by Hodge et al. (2003) but comprehensive illustrated treatments are lacking for most islands. The area of coverage of this contribution includes Guadeloupe itself, with its two main components, Basse-Terre and Grande-Terre, along with nearby satellites Marie-Galante, Les Saintes, La Désirade, Iles de la Petite Terre, Kahouanne, Fajou, and Tête à l'Anglais as well as Saint-Barthélemy and the northern portion of Saint-Martin (the southern portion, Sint Maarten, is a Dutch possession). The latter two islands are separated from Guadeloupe by about 200 km (and by Antigua, Saint Kitts, Montserrat, and other non-French islands), but are administered as dependencies of Guadeloupe.

The book begins with a fascinating historical review of herpetological studies in the region from 1647 through the 20th Century, with coverage of the contributions of naturalists such as L'Herminier and Plée, as well as French and American workers of modern times. This historical perspective is maintained throughout the book, which frequently quotes the observations of early explorers and naturalists and is liberally illustrated by maps and plates from 17th to 19th century natural history works. A short chapter provides a brief geological overview of Guadeloupe and characterizes vegetation types by a combination of elevation and rainfall regimes. The introductory portion of the book closes with the author's consideration of the herpetofauna as a whole. This includes a discussion of the origin of the Lesser Antillean herpetofauna and of the Guadeloupean fauna in particular, an overview of changes to the Pre-Columbian fauna brought about by translocations, extinctions, and extirpations, and finally, a review of threats to the herpetofauna and conservation measures. As elsewhere in the Caribbean, major threats include habitat destruction and introduced species. Some species, including the extinct lizards *Leiocephalus* cf. *cuneus*, *Ameiva cineracea*, and *A. major*, have disappeared since the arrival of Europeans and others, among them endemics, are threatened by the very recent arrival and spread of exotics such as *Osteopilus septentrionalis* and *Iguana iguana*.

The bulk of the volume consists of species accounts for the six frogs, five turtles, 21 lizards and seven snakes occurring in the region. Each species account provides a wealth of information. Under the heading "systématique" the types are identified by museum number and type localities are cited verbatim. The original name and any synonyms are also noted and extensive comments regarding taxonomic and nomenclatural issues are provided. Remaining subsections include: description, répartition, habitat, biologie-écologie, reproduction, and protection. Each account is accompanied by two maps, one showing distribution by island in the Lesser Antilles (with extinctions and extirpations noted) and one providing point localities within the Guadeloupean region. Further, the latter maps distinguish between modern records and those dating from the 19th and early 20th centuries. Fossil localities and unconfirmed records are, likewise, differentially plotted.

Each account is illustrated by color photos of the species as well as line drawings when appropriate. A representative account, that of *Eleutherodactylus johnstonei*, a frog species widespread in the Lesser Antilles, is 12 pages long and includes 17 color photos, a black and white illustration showing stages of development, and a sonogram. In constrast, the relatively recently described endemic *E. pinchoni* is treated in only four pages, with five color photos. *Iguana delicatissima*, a species of special interest to the author, is covered in 20 pages with 26 color photos (including a copulating pair, a specimen swimming under water, and several *I. delicatissima* x *I. iguana* hybrids) and a reproduction of an illustration from the 18th century work of Seba. In all, the book contains hundreds of color illustrations. Many of the photographs were taken in the field and are not as well composed as would be ideal, but all are nonetheless adequate for their purposes.

In general the accounts are detailed and well referenced. Espe-

cially in the case of *Anolis*, up-to-date phylogenetic hypotheses and models of taxic differentiation and faunal assembly are presented and supplemented by illustrations. Many of the natural history observations are original and most of the localities are published here for the first time. As I have recently reviewed the literature on *Thecadactylus rapicauda* (Russell and Bauer 2002) I used this taxon to evaluate the thoroughness of Breuil's accounts. Several Lesser Antillean islands where the species has been recorded (e.g., Sombrero and several of the Grenadines) have not been indicated on the map, and one synonym has been omitted. These minor issues aside, the account cites the relevant sources and adds interesting information on color variation and natural history in the Guadeloupean region. It also identifies some 40 point localities, in comparison with approximately six in the previously published literature.

The fauna is an interesting mixture of endemics (including *Anolis marmoratus*, with six recognized subspecies on Guadeloupe, *Sphaerodactylus fantasticus* with eight subspecies, and *Typhlops annae*, known only from the holotype from Saint Barthélemy), more widespread Lesser Antillean or Caribbean species (e.g., *Gymnophthalmus underwoodi*, *Iguana delicatissima*, *Mabuya sloanii*), and introduced species (e.g., *Osteopilus septentrionalis*, *Pelusios castanea*, *Ramphotyphlops braminus*).

An appendix provides a species list by island along with an indication of the date of each first record. A second appendix lists all Guadeloupean specimens in the collection of the Muséum National d'Histoire Naturelle in Paris. A short glossary defines 47 terms and there are separate indices to the Latin names of amphibians and reptiles, French common names of amphibians and reptiles, other animal names, and plant names. More than 575 references are cited in the bibliography, including many governmental reports and archival sources.

The book is the outcome of 66 weeks of field work by the author since 1987. However, it is much more than this. Breuil has done as thorough a job in his review of the literature and his preparation of maps as he has in the field. The result is a handsome volume that provides an excellent introduction to the amphibians and reptiles of the northern French West Indies and leaves the reader with a sense of both the geological and human factors that have shaped and continue to modify composition of the herpetofauna. The new distributional records, comprehensive bibliography, and detailed natural history data presented by Breuil make this an indispensable reference for anyone interested in Caribbean herpetology. The combination of a two-page English summary and the clear organization of the book should facilitate its effective use by even non-speakers of French.

Until now, except for those who read Urdu (Khan 1993), no recent comprehensive treatment was available for the ophiofauna of Pakistan. As a consequence, most of us had to rely on Malcolm Smith's 60-year old *Fauna of British India*, vol. III, several papers by Mertens from the 1970s, Latifi's (1991) *Snakes of Iran*, and some more recent articles by Khan. This handy-sized guide (15 x 21 cm) with many color pictures, drawings, maps, and keys was thus a much-welcomed publication. However, my initial expectations soon turned into annoyance and amazement at so much sloppiness in one book.

Many diagrams of head scalation (see below) and all distribution maps are poorly executed. The hand-drawn symbols on the charts greatly distract from the potential distributional insight. These illustrations are in sharp contrast to the numerous, mostly excellent snake photos, frequently even of different color phases, shot by various photographers. Another worry is whether the level at which this book is written really serves its principal audience. According to the Introduction the book is aimed at biology and medical students, people concerned with agriculture, forestry and mining departments, and foreign visitors. It would be applauded if all these groups developed a strong ophiological interest, but I suspect that nature-loving tourists and the briefly mentioned (p. 43) amateur herpetologists and terrarium enthusiasts from Europe and the USA will compose the largest section of prospective buyers. They will initially be attracted by the photographs that unfortunately depict only 54 of the 70 species given in Khan's chapter Systematic Checklist of Snakes of Pakistan. More advanced users would welcome a good synonymy which, except for the citation of the original description, is lacking. Such detail may not be required in a field guide, nevertheless, several critical remarks concerning the taxonomy and nomenclature are called for, because the reader does need to know which species is really being discussed.

It is quite a job to distill from this book how many snake species occur in Pakistan. For instance: "In Pakistan, Family Colubridae is represented by 18 genera of 31 species" (p. 76). However, I count 16 genera and 35 species in Khan's Systematic Checklist (pp. 44–46) and there are 15 genera and 33 species discussed in

the text. The problems with the treatment of subspecies (discussed below) aggravate this puzzle. Even though mentioned in Khan's Checklist, *Spalerosophis atriceps* is missing from the species accounts. Only the note about 80 pages later ("Doubtful species of snakes for Pakistan") explains that "*atriceps*" is assumed to be the old-age form of *S. diadema*. *Telescopus rhinopa*, included in the Checklist, is listed as unlikely for Pakistan in "Doubtful species of snakes for Pakistan" (p. 206).

Throughout the text are numerous statements which are at least partially erroneous or simply meaningless. On p. 73: "Pythonidae (Pythons) ... Inhabit thick jungles of southeast Asia, Africa and South America." Well, forget about South America; only *Loxocemus* inhabits Mexico and it is not considered a true python. Or on p. 76 with regard to the Colubridae: "Moderately large snakes with typical snake morphology." What other morphology is there to expect? Further, many colubrids are small, only some are large. Khan reports of *Ramphotyphlops braminus* (p. 62) that "Almost nothing is known about the natural history of this miniature, secretive snake." In reality a great deal is known, including much about its natural history (e.g., Ota et al. 1991). Neither is the body of worm snakes < 150 mm; a dozen species reach > 300 mm, with *Leptotyphlops macrolepis* at 400 mm. On page 69 the author states that "Boas are snakes of moderately dry, more or less sandy areas." This is possibly correct for erycines, but certainly not for boas in general. For *Amphiesma platyceps* "head with large shields," a characteristic of colubrids in general, is provided as a distinctive characteristic of the species. Finally, on page 76: "...colubrids universally share some characteristics: head, neck, trunk and tail are distinct...." This is perhaps so in Pakistan, but not across the world. For example, the large genus *Calamaria*, in which this is definitely not so, springs to mind. This raises the general question if all the data given pertain to Pakistani snakes, or if not, which other sources were consulted.

A strong critique of Khan's *Typhlops* species (Wallach 2000) is listed in the bibliography but not mentioned in the text and Khan, regrettably, uses his original nomenclature rather than Wallach's corrections. Many other species also suffer from nomenclatural and taxonomic problems. *Boiga melanocephala* has previously been considered a subspecies of *Boiga trigonata*. Thus, who elevated it to full species—Khan? Khan (1994) separated *Boiga melanocephala* from *B. trigonata* in his key, whereas earlier (Khan 1982) he regarded it as a subspecies. Confusing. *Coluber rhodorachis* (Jan, 1865) should be attributed to (Jan in Filippi, 1865) as Filippi was the author of Viaggo Persia. *Coluber ventromaculatus* was described by Gray, not Gray & Hardwicke. The common name of *Natrix tessellata* is usually given as Dice Snake, not Blotched water snake (p. 130). The single, almost century old, report for Pakistan of this snake by Wall (1911) should have been fully investigated. On page 206 *Natrix tessellata* is called *Xenochrophis tessellata* by Khan, and Wall (1923) is referenced. This is one of the many cases in which a proper synonymy would be helpful, but alas "In present work, such delicate taxonomic matters are avoided" (p. 76). Wall (1923:604) referred to this species as *Nerodia tessellata*, and the only *Xenochrophis* listed by him was *cerasogaster* on p. 600, so this must be a *lapsus* by Khan. Typically *Pseudocerastes bicornis* is listed as a synonym of *Pseudocerastes persicus* (e.g., Golay et al. 1993; Joger 1984); not here, so who elevated it to full species? Khan? And if so, where was the action published? Several forms previously treated under *Naja naja* are indeed now considered to be distinct species, such as *Naja oxiana*. It would have been advisable to mention who recognized these as species (Wüster and Thorpe 1992; Wüster 1996), and that Deraniyagala (1960, 1961) came to the same conclusion even earlier.

Khan has difficulties with the gender of genera: (p. 79): *Argyrogena fasciolatus* = *Argyrogena fasciolata* (*Argyrogena* is of the feminine gender); on p. 46 in *Spalerosophis schirazianus* the masculine form of the species name is correctly used, but on p. 151 we find *S. schiraziana*. *Pseudocyclophis persica* = *Pseudocyclophis persicus* (masculine gender) and the original reference is incorrect; it is not *Pseudocyclophis walteri* Boettger, 1888, but *Cyclophis persicus* Anderson, 1872. Oddly, the listing is correct—including the original author—in the Systematic checklist, but incorrect elsewhere in the book (e.g., pp. 119–120). The use of subspecies is inconsistent and confusing: at first it appears that subspecific names are not given when only the nominate form occurs in Pakistan (for example *Python molurus*), but *Xenochrophis piscator piscator* and *Bungarus caeruleus caeruleus*, for example, contradict this, as does the caption to Fig. 27: "*Python m. molurus*." Though both forms are mentioned in the checklist, it remains unclear what characters differentiate *Coluber k. karelini* and *Coluber k. mintonorum*. Neither is the subspecies *Coluber rhodorachis ladacensis* treated. In the key (p. 185) to species and subspecies of *Echis*, *E. multisquamatus* and *E. pyramidum* are treated as species, but in the species accounts the former is dealt with as a subspecies of *E. carinatus* (on p. 186 and in map 18), and the latter has completely disappeared.

It is nice to see type localities mentioned, though contradictory if the book is focused on non-taxonomists as the author's remarks seem to imply. However, information is lacking from some of the type data. For example, the type locality of *Coluber rhodorachis* is not just "Persia (Iran)," as this was restricted forty years ago to Shiraz (Kramer and Schnurrenberger 1963:501). And when such a restriction has been noted, as in *Lytorhynchus paradoxus*, we would like to know the author responsible, otherwise it suggests an action by Khan in this book.

Though not being a native English speaker, I often stumbled across pieces of very awkward English. Sometimes an unintended pun occurs ("...catching a hooded cobra alive needs much experience, it is advised to be killed before catching one") (p. 33), but mostly the problems are spelling or phrasing errors such as "pray" instead of "prey" (p. 73), or "with 2–3 supralabials in eye," rather than "contacting the eye" or "entering the orbit" (this slip occurs often). In other places there are strange sentences like "Young ones are hatched after 58–60 days of." (p. 73; one assumes that the word "incubation" is missing here), and "The authority of Dr. Wall is sufficient to included this species in the fauna of Pakistan" (p. 206). The definite and indefinite articles are often missing in sentences (e.g., p. 76: "They are heterogeneous assemblage of snakes, status of several species is hotly debated," "In present work, such delicate taxonomic matters are avoided," and "Family Pythonidae is represented..."

Except for Figs. 6b and 12, all lateral views of head pholidosis sketches are called "Head: latrum" (in Fig. 8 and Fig. 10 the lateral view is even labelled "ventrum!"), and the dorsal view "Head: dorsum." While the latter might be acceptable, "latrum" is an

incorrectly formed, semi-Latin word.

Typographical errors abound; here I give just a few examples. The layout of the keys is fairly confusing with sentences inexplicably jumping to the next line (Key to the families [p. 49]: first couplet of question 1, 4, 7 and 8; Key to the genera [pp. 50–51]: both couplets of the first question; and in various places in Key to the species [pp. 53–57]). The alignment in the Checklist is erratic. Because of such mistakes the key with which body fragments of snakes can be identified (an interesting addition) is practically useless. Incorrectly used italics also occur: (p. 73) *Coluber molurus Linnaeus*, (p. 104) species names in the legends of Table 4 not in italics, (p. 215) *Boiga trigonata ands B. melanocephala*, as do simple slips: (p. 75) Thid [=This], (p. 112) "…and In Pakistan…" [unjustified use of capital letter], (p. 175) infral-abials, (p. 175) *Pelamis s platurus*, and (p. 211) 9. 1Subcaudals. Editorial lapses are suggested by mistaken use of small capital letters in localities of, for example, *Lytorhynchus maynardi* – "Koh-Malik-do-KHAND" (p. 109) and *Echis carinatus sochureki* "Band Kushdil KHAN near Pishin" (p. 186).

In the Bibliography, which uses small caps for authors names, Christy, Cogger, Schmidt, FitzSimons and Wall all have only initial caps. Khan & Khan (1996) is listed twice (p. 246 and 247) and this section, like the rest of the book, contains numerous other typos. Are such slips so terrible? No, but they add to the general inaccuracy and greatly undermine confidence in the biological data presented. Only in the rarest cases are citations to different works by the same author in the same year distinguished in the text (e.g., Khan & Tasnim 1986b on p. 133), and this system is never used in the Bibliography. It is unclear whether all the publications listed in the Bibliography were actually used in the book (I became tired of scrutinizing all the mistakes), but certainly a number of those mentioned in the text are not found in the list of references. Having checked pp. 13–17, I find seven citations lacking: Burton (1973), Vogel (1926), Gharpurey (1962), Buffetaut & Ingavat (1985), Powal (1979), Adamson & Shaw (1986), and Jaeger et al. (1989), and one misspelled (Mahinder vs. Mahendra).

The Index indicates that the account of the colubrid *Enhydris pakistanica* is found on p. 173 where, however, the unrelated sea snake *Enhydrina schistosa* is actually treated. *Coluber v. ventromaculatus*, *C. v. bengalensis*, and *C. v. indusai* are missing from the index all together.

While leafing through the book for the first time, several of the black-and-white scalation drawings looked vaguely familiar. It soon became clear why: the great majority were traced in an amateurish way, without any acknowledgment, from Smith (1943). I did not recognize them immediately because the details of pholidosis and patterning were frequently given in separate drawings, the latter often especially clumsily executed as compared to the fine originals (e.g., Figs. 44c, 51b, c, 52c, 54c). In the following cases Khan's figures could be directly attributed to an original in Smith (1943): Figs. 9a, b from Smith's Fig. 35 (lateral and dorsal views; Smith (1943) acknowledged Boulenger (1890) for this figure, but Khan even had the audacity to add his monogram MSK to his tracings); 10a, b from 33 (here the heat-sensitive pits are lost!); 44a, b, c from 111C; 47 from 89; 51a, b, c from 76A and 77A; 52 from 115; 54 from 49; 56 from 51; 57a, b from 100B, C; 58 from 96A, B; 59 from 96C or D; 122b from 145 (middle drawing); 124 a, b from 151A, B; 127a, b from 153A; 128b from 154B; 128c from 154C; 128d from 154 (in Smith's fig. 154 Boulenger is again acknowledged); 129a from 156A; 129b from 156C; 130a from 155B (but, admittedly, the rest of the head pholidosis has been newly added); 130b from 155A; 130c from 155C; and 131 from 157 (again acknowledged by Smith as derived from Boulenger 1890), in which the addition in Khan's tracing is a line pointing to the heat-sensitive pit (although this is not identified in either the text or the figure legends). The remaining black-and-white figures might be originals (but one is understandably suspicious). They are Figs. 11, 12, 45 (containing the monogram MSK; these drawings are good!), 46, 48, 49, 50, 53, 55 (one of the poorest drawings), 61, 121, 125 and 126. The book would have been much improved had the older original drawings of Boulenger (1890), Pope (1935), and Smith (1943) been included rather than bootlegged.

It is disappointing that photos for about one fifth of the snakes are absent. This is particularly surprising where local forms recently described by Khan are concerned (e.g., *Typhlops ahsanai* [should be spelled *ahsanuli*], *Coluber rhodorachis kashmirensis*, *C. ventromaculatus indusai*, *Bungarus sindanus razai*). In the case of Khan's *Typhlops ductuliformes* and *T. madgemintonai* (misspelling of *madgemintonae*) barely recognizable preserved specimens are depicted. Two photographs seem to be of species other than those mentioned in the legends: Fig. 14 is not *Ramphotyphlops braminus* (it looks like an African *Typhlops*), and Fig. 148 is a *Macrovipera lebetina*. The latter photo is taken from Fig. 3, opposite page 48 of Trutnau (1981), where it is also misidentified. It is unclear why Figs. 150–152 depict two different subspecies of *M. lebetina* (viz. *cernovi* and *obtusa*) while the ambiguity on the status of the eastern forms of the species (David et al. 1999) has not yet been clarified; here Khan just adds to the confusion.

The numbering and placement of the maps throughout the book is rather curious. Partly this is caused by including the data of more than one species per map and reprinting the map near the species concerned. Thus map 5 is found on pages 80 and 120 (there following map 12), map 19 is on pages 188 and 190, and map 20 on pages 183 (following map 17 and preceding map 18) and 205. Incomprehensibly, map 10 (p. 130), presenting distributional data for *Xenochrophis sanctijohannis* and *Natrix tessellata* (text on pp. 129–130) is in between map 15 (p. 126) and map 16 (p. 135). There are two different maps numbered 13 (on pages 122 and 125); the latter one should have been numbered 14 (which is otherwise missing) and is indicated as such in the text. On map 4 *Amphiesma platyceps* is either lacking (no separate symbol) or is lumped under *A. sieboldii*.

Despite my many criticisms, there are positive sides to the guide. The notes contain breeding data that are often new and pertinent to the region, although juicier natural history data could have been included. For instance, it is nice to know that *Naja naja* lays 12–30 eggs but as this is the only snake that makes a real nest, why not mention it here? Another plus is the indication of the species' ranges in Pakistan. This will likely stimulate further faunal research. Finally, pages 218–231, with information on snake folklore, contain interesting ethnological information, which is often sadly ignored in similar regional works.

Summarizing: a laudable attempt, poorly executed. Much more information can be found in Smith (1943), which provides much

better original drawings, plus lots of data on pholidosis. It is unclear whether Khan's data on sizes and pholidosis stem from actual measurements on Pakistani snakes, or if these are just transcribed from other works. If the former, the book's inherent value would be increased. A major lack of editorial control is apparent, concerning scientific content, figures, proof reading, and a disregard for proper English. Perhaps for the latter aspects the publisher is as much to blame as the author.

Nonetheless, the book has nice production values and decent species accounts, and considering what is currently available on the Pakistani snake fauna, it probably should be bought by anyone with an interest in the region. However, given the sea of inaccuracies it contains, the volume should not be used as a work of reference. Still, one should appreciate Khan for his mission to make his fellow man understand (p. 8) that "Snake is man's friend, do not kill it!"

Wide distribution gaps of several taxa reflect our poor knowledge of the herpetofauna of central Peru. In an attempt to improve our understanding of the diversity of amphibians and reptiles in this region, Edgar Lehr presents in this book the results of his field work in Peru between 1997 and 2001. Lehr surveyed 42 localities along a 470 x 50 km transect extending from the Pacific coast to the Amazonian lowlands at 10° south latitude and passing through four Departamentos (Ancash, Huánuco, Pasco, and Ucayali) and five ecological regions.

The introductory chapter includes a general overview of Peru's megadiversity and a brief, but informative, outline of the history of herpetology in Peru, including major contributions since the 19th century (e.g., Tschudi 1845; Werner 1901). As shown in figure 1 (p. 10), the number of publications on Peruvian herpetofauna has increased dramatically during the last quarter of the 20th century. The chapter then focuses on Peruvian geography, physiography, climate, and geology, and includes short descriptions of the ecological regions included in the transect. More than 20 good-quality landscape pictures reveal to the reader the great variety of habitats in which the species included in this book were collected. Lehr continues with a detailed description of materials and methods including a list of all collecting sites (pp. 25–27). Political units, coordinates, elevations, life zones, and collection dates are provided for each of the 42 localities included in the transect. In addition, collecting and preservation techniques, as well as methods of data analysis are described.

With 120 pages, the third chapter constitutes the main section of the book. It includes accounts of species and a number of large tables. Table 3.2 (6 pp.) contains a list of all species collected with their respective ecological region, elevational distribution, and other collection data. Table 3.4 (9 pp.) provides eight scale counts for all collected specimens of snakes, and Table 3.5 (10 pp.) includes yet another list of species with their distribution among the 42 localities of the transect. Most species accounts are very short and contain general information on distribution, remarks, and color photographs. Accounts of some species (e.g, *Bufo spinulosus*, *Proctoporus*) are more extensive than others and contain informative diagnoses and/or information on natural history and ecology. Except for a few poorly-taken photographs and some minor spelling errors (the name *Phyllomedusa* is misspelled in the figure captions of all photographs on p. 54; caption "*Phrynopus dagmarae*, ..." does not correspond to the figure on p. 63), the color pictures make this book a useful guide for anyone working with amphibians or reptiles from central Peru. Additionally, good-quality drawings of *Bufo chavin*, *Phrynopus dagmarae*, *P. horstpauli*, *P. heimorum*, *P. kauneorum*, four new species of *Proctoporus*, and *Leptotyphlops alfredschmidti* are provided. General information on 15 new species (9 amphibians and 6 reptiles) is included, although these species are not formally described in this book. An update to previous lists of amphibians and reptiles in Peru (Carrillo de Espinoza and Icochea 1995; Morales 1995; Rodríguez et al. 1993) is also provided on pages 113–114. In addition, 51 new records of reptiles and amphibians are reported for Departamentos Ancash, Huánuco, and Ucayali. This chapter ends with a brief discussion on biogeography. Number of species and endemism are compared among all different life zones included in the transect at the specific, generic, and familial levels.

The last chapter is a discussion that mainly addresses the necessity for more studies on diversity of the Neotropical herpetofauna. Several surveys in previously unexplored areas in Peru have led to the discovery of 63 species of amphibians and 22 species of reptiles in the last eight years. This increase in the number of species of amphibians (379) and reptiles (387) probably modifies the ranking of Peru among the megadiversity countries. With 241 species of amphibians and 298 reptiles, Peru was ranked number 7 and 12 for amphibian and reptilian diversity, respectively (Mittermeier et al. 1997). There are still many regions to be explored in Peru, and it is very likely that unknown species occur in these areas. This book is a great contribution to the study of biodiversity in South America and it will be very useful to students, amateur biologists, ecotourists, or anyone interested in Peruvian herpetofauna.

The increasing interest in the herpetology of Indochina over the last two decades has led to a growing number of publications reflecting the results of faunistic and taxonomic research. Indeed, we are witnesses to a new era in Southeast Asian herpetological research. In addition to numerous papers presenting new records and descriptions of new species, several large-scale monographs on the herpetofauna of Southeast Asia have also appeared (e.g., Nguyen and Ho 1996; Manthey and Grossmann 1997; David and Vogel 1997). The rich and diverse fauna of amphibians and reptiles of Vietnam is no exception. Ziegler's book on the amphibians and reptiles of a protected area of lowland rainforest in Ha Tinh Province is a valuable addition to this literature.

The introductory chapter starts with a detailed description of the history of herpetological research in Vietnam and an explanation of the main goals of the study. In the following text readers learn about the geography, physiography, climate, vegetation, and biogeography of Vietnam in general, and of the Ky Anh-Ke Go protected area of Ha Tinh Province in particular. This is one of the most endangered wilderness areas in Vietnam and served as the site of the author's field work and collecting during the periods of June–September 1997 and August–October 1998.

The Material and Methods chapter includes a description of all of the collecting, preservation, voice recording, and molecular techniques employed. The main part of the text consists of individual species accounts detailing the characteristics of 31 species of amphibians and 58 species of reptiles. Species accounts contain the following information: Latin name, describer, year, reference and

type locality, common name in German, specimens examined, general distribution, description, ecological notes, sonogram (for frogs), and taxonomic comments. All species accounts are accompanied by excellent color photos. The systematic section is followed by several short chapters with general considerations on biodiversity (species richness and abundance), ecological diversity (comparative analysis of spatial, temporal and trophic distribution, general patterns of reproductive biology), and zoogeography. The last chapter is devoted to the very real problem of amphibian and reptile trade and its role in the decline of these animals in Southeast Asia.

This monograph is a perfect example of a detailed characterization of the herpetofauna of a restricted region based on intensive and efficient research. The comprehensive inventory is enriched by detailed documentation of such features as hemipenis structure for male squamates and vocalizations for frogs and geckos. It is also necessary to point out that the technically superb and very attractive photos are themselves important sources of information and can be used for field identification. They illustrate important species characteristics and include biologically relevant field shots, such as those of frogs calling and in amplexus, and snakes in sleeping positions (e.g., Fig. 348, p. 224).

We have only a few critical remarks. Firstly, strictly speaking, the book deals not only with lowland rainforest, as the title implies, but also with foothill forests. In addition, a number of taxa have been identified only to the generic level (e.g., pp. 42, 209, 219, 243). Obviously future resolution of these identifications would be desirable and we have no doubt that the author is continuing his investigation of these species. Nonetheless, we suspect that the species list is incomplete and that further field work would add to the documented diversity of the site. For example, megophryids are very poorly represented (only one species) as are microhylids. The latter group of frogs was probably incompletely sampled because field work was not conducted during all seasons of the year. It is also likely that more scincids, colubrids, and elapids (e.g., *Calliophis*) may be present. Finally, the frog on page 60 (Fig. 69) identified as *Microhyla* cf. *annamensis* is most probably *M. berdmorei*.

Despite these minor corrections and complaints, we conclude that Ziegler's monograph is a valuable supplement to the herpetofaunal literature of Indochina. It will be useful for anyone concerned with the amphibians and reptiles of Vietnam or other regions of tropical Asia.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.html>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor or Managing Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR Treasurer (Dr. Theodora Pinou; contact information on inside front cover) or from the SSAR web page (http://www.ssarherps.org/pdf/Adrates.pdf).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Donald Schmitt, SSAR Membership Office, P.O. Box 253, Marceline, Missouri 64658, USA. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below), regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 760	$320

A Radio Transmitter Belt for Small Ranid Frogs

ERIN MUTHS
USGS-Biological Resources Division, Fort Collins Science Center
2150 Centre Avenue, Bldg C, Fort Collins, Colorado 80526, USA
e-mail: erin_muths@usgs.gov

Radio telemetry is a useful technique for gathering information about amphibians when associated caveats are applied (Bartelt and Peterson 2000). A number of designs for transmitter attachment are available for larger anurans including a harness-type attachment (van Nuland and Claus 1981) and various belt designs (Bartelt and Peterson 2000; Rathbun and Murphey 1996; Waye 2001). Attaching radios to small anurans is particularly problematic because of their mass, shape, and delicate skin. Small radios, 0.61 grams or less, are available, although battery life is usually only 2–3 wks (e.g., Holohil Systems Ltd; Carp, Ontario, Canada[1]). The issues remaining are the weight and longevity of the attachment system, ease of application to the animal, and effect on the behavior and health of the animal.

Here I describe an attachment assembly tested in the laboratory on juvenile leopard frogs (*Rana pipiens*) and used on wood frogs (*Rana sylvatica*) in the field.

The goal of the field study was to fit radio assemblies to 8 wood frogs (4 males and 4 females) and to follow them for approximately 2 wks (the life of the battery) during and immediately after the breeding season (May–early June). Male wood frogs generally breed in their second spring when they are between 34 and 40 mm snout–vent length (SVL); females generally breed in their third spring when they are between 45 and 54 mm SVL (Hammerson 1999). Currently available attachment methods were unacceptable for these small ranid frogs.

I used Holohil BD-2A transmitters (0.61 g). The transmitters were configured so that the battery was placed on top of the transmitter rather than in front of it (Fig. 1b). In earlier trials, using the belt system described by Bartelt and Peterson (2000) and the original, linear arrangement of the transmitter, frogs were unable to properly orient themselves in the water. This was because the length of the assembly system made the transmitter ride too far up on the frog's back and because the belt material was too bulky.

I used very fine craft elastic (gossamer floss, B. Toucan, Inc., US $1.64 for 5 yds) and size 14 Japanese glass seed beads in olive

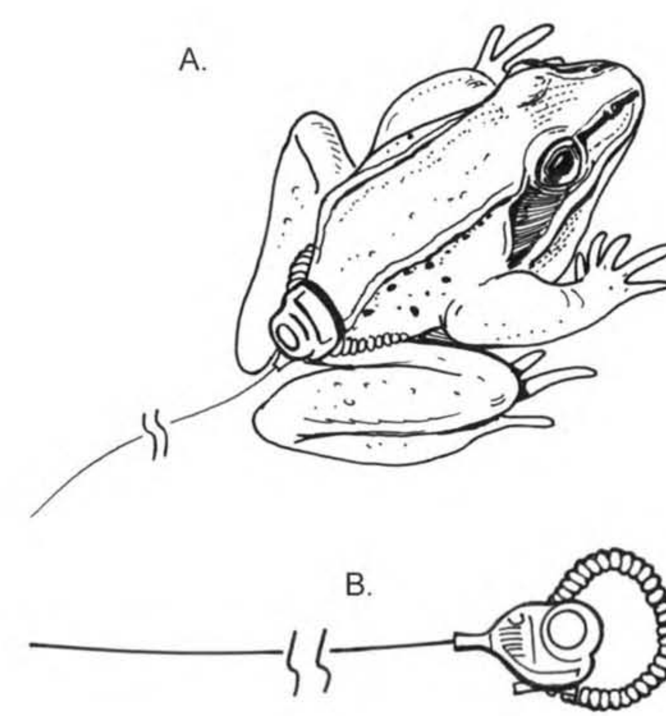

FIG. 1. (A) Male wood frog with transmitter and belt assembly. (B) Sketch of belt assembly with radio for small ranid frogs.

matte (F458, US $3.45 for thousands) to make the belt. The elastic was threaded through the small attachment tube on the transmitter pack and beads were strung on the elastic. The elastic was tied in a knot and the knot stuffed into the tube on the pack. This small belt (Fig. 1a) was able to stretch enough to be held open by 2–3 fingers while the back legs of the frog were pushed through with the other hand. It was easy to determine if the belt fit correctly: too tight and the frog's skin was pinched and it was unable to move naturally, too loose and daylight was visible between the frog and the belt. When fitted properly, the belt should roll easily when manipulated. Because we were interested only in relatively small movements, in and near the breeding pond, I shortened the 14 cm whip antennae to 9.5 cm. This reduced the range of the transmitter and the mass of the assembly (slightly), but more importantly, reduced the possibility of entanglement for the frog.

I used 2 captive, juvenile leopard frogs to test the harness prototype before the 2002 field season. Both animals were ca. 9 g. Animals were housed together in a 15 gal. aquarium with rocks, plants, and an upturned plastic tub for shelter. The aquarium was set on an angle to provide aquatic and non-aquatic habitat. Frogs were fed small crickets, ca. 8 per animal per week.

After a number of fitting trials, a belt assembly (22 beads) with dummy transmitter (0.73 g total mass), was placed on leopard frog 1 (ca. 9 g, 41.3 mm SVL) on 10 March. The other frog was approximately the same size and was not fitted with a belt. The frogs were checked 2–4 times daily. Hiding and feeding behaviors were noted and frog 1 was assessed visually for abrasions. The assembly was removed on 14 and 18 March to check for abrasions manually and then replaced. I isolated frog 1 to confirm that it was eating and defecating 18–25 March. The assembly was removed on 7 April.

Pilot data collected in 2001 provided an estimate for our expected size of individuals: mean mass = 8.7 g, mean SVL = 43.1 mm (N = 8). Our criterion for selecting individuals to carry the transmitter was adult animals ≥ 8.5 g. This follows the general rule that transmitters and assembly systems should not exceed 10% of total body mass (Richards et al. 1994).

Neither the movements of the two leopard frogs around their environment, nor their appetites appeared to be affected by the assembly on frog 1. Both belted and non-belted frogs consumed crickets (7 and 8 crickets, respectively) and produced approximately equal amounts of waste (3 and 4 pellets, respectively), when housed together and separately. On 7 April, a small (2–3 mm) cut was found underneath the belt on frog 1. The assembly was removed and the cut cleaned. The assembly was not refitted. The leopard frog tolerated the belt assembly for 4 wks, about 2x longer than I expected the batteries to last. It was not until the fourth week that there were any signs of abrasion. After the belt was removed, the wound healed within 2 days.

In May we fitted 11 different wood frogs with transmitters (Table 1, Fig. 1) at the field site. The smallest frog fitted was 8.5 g and the complete belt assembly with 22 beads weighed 0.73 g, 8.6% of the frog's mass. Of these, 5 frogs (3 M and 2 F) shed the belts soon after they were fitted (≤ 4 days) and 6 frogs retained the belt assembly from 7 to 30 days (mean = 21 days, males; 16 days, females). There is a relationship between mass and the number of beads needed for the belt ($R^2 = 0.81$) (Fig. 2), but there are too few data to build a reliable predictor.

Animals were located 3 times daily (1200, 1800 and 2400 h), but inspected visually (for abrasions or problems with the belts) only once per 24 h period. In 4 of 5 cases the animals that shed their belt assemblies within 24 h of attachment were smaller than their counterparts that retained their belts of the same number of beads. Detectability of the transmitter signal was not related to the length of the whip antennae although transmitters varied in battery life (Table 2). All females fitted with belt assemblies were gravid and lost appreciable mass (0.9–4 g) over the course of the study after their eggs were deposited. Males either lost or gained minor amounts (± 1–1.5 g) except for one. This male retained the belt assembly for 22 days before any abrasions were noted. At that point, the belt was removed, the frog weighed and the small abrasion was treated with Bactine®, and a second belt was attached. When the assembly was removed on 31 May, 10 days later, the

70650	164.207	19	M	45	R

* transmitter was turned off with magnet when not on frog.

frog had lost 2.5 g (23% of its mass determined on 22 May).

Advantages to this system are its weight, flexibility in sizing, and low cost. Secondarily, the color can be adjusted easily for the target species given the wide variety of bead colors available. The belt also has the potential to tear away if the frog becomes entangled in vegetation, although this was not tested in the field.

The weight of the assembly depends on the number of beads used in the belt. The difficulty in fitting the belt was in estimating the number of beads to use. The relationship between mass and number of beads serves as a rough guideline to determine the length necessary for the belt (Fig. 2).

The process of assembling the belt system requires the use of tweezers or a fine needle to thread the beads. This can be a disadvantage when ambient air is cold enough to make numb hands an issue. Collars can be assembled before the field session, but a certain amount of fine-tuning when the frogs are captured should be expected.

This belt assembly is recommended for relatively brief studies where long-distance movements are not expected. We found no frogs with skin irritations or abrasions during the first three weeks of this study.

Acknowledgments.—I thank Rocky Mountain National Park for research support, Dale Crawford for artwork, Mica Steele, Suzanne Rittmann, Sarah Street and Rick Scherer for material suggestions. Rick Scherer offered valuable input during field-testing, Jason Helvey provided tenacious radio tracking and insightful suggestions regarding field protocols, and Andrea Moore helped with frog husbandry.

To clarify the status of an endangered species, it is necessary to estimate population size. Blaustein et al.(1994) recommended mark and release as the best method for assessing populations. Toe clipping is commonly used as a mark-recapture method for mammals, reptiles, and amphibians (Demaynadier and Hunter 1998; Dole 1965; FitzGibbon 1997; Lips 1998; Loredo and Van Vuren 1996). However, Clarke (1972) found the probability of recapture decreases as the number of toes removed increases in *Bufo woodhousei fowleri*. Golay and Durrer (1994) marked 96 *Bufo calamita* and found that 12 out of 66 recaptured animals had infections arising from toe-clipping. Lemckert (1996) pointed out that generalities about the effects of toe-clipping on anurans are difficult to make. Because of these problems we regarded the toe-clipping method as unsuitable for endangered species.

Recently, a photographic technique that identifies individuals from their spot pattern has been used for spotted salamanders, *Ambystoma maculatum* (Loafman 1991), and leatherback turtles, *Dermochelys coriacea* (McDonald et al. 1996). This technique has several advantages, as the animals are not injured, the technique is easy to use, and it is inexpensive (Doody 1995). Therefore, this method should be useful for endangered populations.

The Japanese Environment Agency recognized the daruma pond frog, *Rana porosa brevipoda*, as a threatened, vulnerable species in 1997. Moreover, the Forestry Department, Hiroshima Prefecture Office, recognized *Rana porosa brevipoda* which live in Hiroshima as an endangered species in 1995. In the Hiroshima prefecture, *R. p. brevipoda* occurs only in a few sites, where the population was reduced by conversion of its habitat to new rice paddy fields. A population that was reintroduced after the reclamation of the rice paddies is being monitored (Okochi et al. 1997). To avoid hurting the frogs, Okochi et al.(1997) used direct counts of individuals in fields as an index of population size. However, this method is unlikely to provide an accurate estimate. To solve this problem, we estimated the population size by photographic

identification of individuals, and compared this estimate to that of the direct count.

The study was carried out in rice fields in Kisa Town, Hiroshima prefecture, southern Japan (132°59'E, 34°42'N). The study site is a typical rice paddy in a drainage basin, and contains many rod-row plots surrounded by levees and concrete ditches. The site is dry from harvest in September until planting in May. On 4 and 11 October 1998, after reaping, seven to eight people walked through the study paddies and searched for *Rana porosa brevipoda* under the rice straws in each rice rod-row plot. Some of us have studied this species since the 1980s, and confirmed that the dot pattern does not change over several days. Because individual frogs have a distinctive pattern of black dots on the body, the pattern can be used to identify individual frogs. The pattern on each frog was photographed from three sides (the right and left flanks, and the back) and the individual was then released back into the rice paddy where it was captured. After these field surveys, we checked the pictures directly three times, and identified recaptured frogs. Each of the tests were evaluated entirely by different people, and each of their estimation from the photographs corresponded to the other.

We found 76 froglets on 4 October and 114 froglets and 6 adults on 11 October. Fourteen froglets were recaptured on the second occasion. Of these, nine were recaptured in the same paddy rod-row plot as in the first survey, three were found in the adjacent plot, and two were found two plots away from the original site. No recaptured frogs crossed the 30–40 cm deep concrete ditches in the fields (Fig. 1). This suggests that the concrete ditches might be barriers for froglets. Therefore, the number of young frogs in each group of rice plots enclosed by concrete gutters was calculated separately using the simple average and Bailey's estimate (Donnelly and Guyer 1994).

Bailey's estimate =

$$\frac{(\text{Froglets captured on 4 Oct})(\text{froglets captured on 11 Oct} + 1)}{(\text{Recaptures} + 1)}$$

For three groups of rice paddies, the simple average of the direct count on the two survey days was 19.5, 49.5, and 26 froglets and the overall average was 95. The estimated populations were 133.3 ± 61.5, 197.8 ± 52.3, and 232 ± 109.9 (± 1SE). The total estimated population was 563.2, which is 5.9 times larger than the simple average.

The photographic technique was used successfully to recognize individual *R. p. brevipoda* by their spot patterns and thus to estimate population size. We found 196 uniquely-patterned individual frogs. Such a population-size difference means that the true population may be bigger than estimates based on a direct count. Because the spot pattern of *R. p. brevipoda* changes with growth, the photographic technique is only useful for identification in the short term, and how long it is effective has not yet been determined.

It is important to determine the results of conservation efforts and to develop better conservation programs. We believe that this photographic identification technique based on spots is suitable for monitoring endangered populations.

Acknowledgments.—We are grateful to Masami Hasegawa, Kinji Fukuyama, Junichi Ohki, and other volunteers for their assistance in the field. Thanks are also due to the Forestry Department, of the Hiroshima prefecture Office, and the Agriculture Department, of the Miyoshi town Office for supporting the fieldwork.

Decline and Local Extinction of the Western Toad, *Bufo boreas*, on Southern Vancouver Island, British Columbia, Canada

THEODORE M. DAVIS*
and
PATRICK T. GREGORY
Department of Biology, University of Victoria, P.O. Box 3020 Victoria, British Columbia V8W 3N5, Canada

**Corresponding author. Present address: Biology Department, Camosun College, 3100 Foul Bay Road Victoria, British Columbia V8P 5J2, Canada e-mail: tmd@telus.net*

Concern over the decline and loss of amphibian populations has lead to repeated calls for 1) routine long-term monitoring of amphibian populations and 2) more detailed studies of their autecology (Alford and Richards 1999; Blaustein et al. 1994c; deMaynadier and Hunter 1995; Pechmann and Wilbur 1994). These approaches are complementary because long-term data are necessary to unambiguously identify unusual declines, and detailed species-specific knowledge of life history, behavior, and population ecology is needed to identify the causes, likely outcomes, and means by which such declines might be mitigated should they occur (Alford and Richards 1999; Blaustein et al. 1994c). Detecting trends in amphibian populations is notoriously difficult because annual recruitment is highly variable, and the distribution of individuals fluctuates seasonally as breeding aggregations form and microhabitat availability changes (Alford and Richards 1999; Pechmann et al. 1991). Also, many, perhaps most, amphibian populations persist because of metapopulation dynamics, and temporary local stochastic extinctions might be common (Alford and Richards 1999; Blaustein et al. 1994c). Furthermore, a population might be a reproductive source or sink, but its status in any particular year unpredictable and ephemeral (Hanski 1999; Pulliam 1988). A site with apparently suitable habitat but lacking a particular species might represent a temporary local extinction, a disruption of metapopulation dynamics, may have never been occupied because of its isolation, or might be deficient in some essential combination of resources and conditions.

One approach to resolving these problems is to use historical records as a baseline for comparison with current patterns of distribution and abundance (e.g., Corn et al. 1989; Drost and Fellers 1996; Fisher and Shaffer 1996). Historical records are typically limited in scope. However, when combined with knowledge of specific human-induced alterations of habitat they can help identify declines and extinctions, focus monitoring and research efforts, and suggest which actions might be effective in restoring populations and preventing additional losses. Here we report on a local extinction of the western toad, *Bufo boreas*, at a relatively undisturbed site on southern Vancouver Island, British Columbia, Canada. Based on field notes and other information, this site supported a population of *B. boreas* in the 1970s, but no toads have been seen since 1983, despite intensive searching in 1997–2002. The reasons for this loss are unknown, but the introduction of exotic fish and habitat fragmentation may have been contributing factors. Although there is abundant evidence that population declines and local extinctions of *B. boreas* have occurred throughout much of the southern part of its range (see below), this is the first such report from Canada.

Of the several amphibian species that have suffered population losses or declines in western North America, the Western Toad, *B. boreas*, represents one of the most dramatic and best-documented examples (Corn 1994). Corn et al. (1989) failed to find *B. boreas* at 49 of 59 (83%) historical sites in Colorado and Wyoming in 1986–1988, although toads were found at two sites where they had not been recorded previously. Carey (1993) reported that 11 populations of *B. boreas* disappeared between 1974 and 1982 in central Colorado. Other surveys in Colorado found fewer populations than existed previously (Corn 1994; Corn and Vertucci 1992), and the elevational range of breeding sites appears to have been reduced in Colorado and Wyoming (Livo and Yeakley 1997). Olson (1992) described declines of two *B. boreas* populations in the Oregon Cascades, and Blaustein and Olson (1991) described mass mortality of toad eggs at a third site. In Yosemite National Park, surveys in 1915 and 1919 described *B. boreas* as "exceedingly abundant," but only small numbers were found in 1992, and of eight historical sites, *B. boreas* was found at only one (Drost and Fellers 1996). Similarly, Fisher and Shaffer (1996) described the decline of *B. boreas* in California's Central Valley. Disease, habitat modification, susceptibility to UV radiation, acid precipitation, and predation have been suggested as possible causes for these declines, but unequivocal evidence is lacking (Blaustein et al. 1994a,b; Carey 1993; Corn and Vertucci 1992; Olson 1989). Despite these reports from the United States, there are no published reports of population trends of *B. boreas* in Canada.

Jordan Meadows (48°34'N, 123°53'W) is an undisturbed marshland adjacent to Weeks Lake (elevation 518 m), ca. 40 km NE of Victoria, British Columbia. These extensive wetlands (ca. 0.5 x 4.5 km) support abundant wildlife and are dominated by plants typical of marshlands on southern Vancouver Island, especially hardhack (*Spiraea douglasii*) and Labrador tea (*Ledum groenlandicum*). Jordan Meadows proper appears to be undisturbed, and the forest immediately surrounding the meadows was uncut until 1999. However, an extensive network of logging roads exists throughout the area, and logging activities and clearcuts are common. Recent (1999) logging has extended to the edge of the meadows.

From 1975 to 1979, one of us (PTG) saw 1–5 *B. boreas* on each of 16 visits he and his companions made to Jordan Meadows (July 1974: 1 visit, 3 h; May–July, 3 visits, 14.5 h; June–September 1976, 2 visits, 3.75 h; April–September 1977, 7 visits, 12.8 h; May–September 1978, 3 visits; 13.4 h; April–June 1979, 3 visits; 8.2 h; total search effort: 19 visits, 53 h). During this period, toads were found at the rate of at least 0.8 toads h^{-1}. Toads were found in the meadows proper and in forested upland areas near the meadows. From 1980 to 1994, fewer visits were made to the meadows (5 visits, 6 h), and during this period, only one juvenile toad was found.

Despite intensive daytime searching in Jordan Meadows in 1997–2001, including monitoring six pitfall traps in 1997, no toads

were seen. TMD and assistants used visual encounter surveys (Heyer et al. 1994), walking back and forth across meadows and making thorough searches of the margins of streams and ponds. We also searched small ponds and streams for tadpoles and looked for toads basking on logs. We searched the same areas where PTG found toads in the 1970s, but the search effort in 1997–2002 was much more intensive (April–August 1997: 11 visits, 38.5 h; May–July 1998: 7 visits, 19 h; May–August 1999: 6 visits, 14.3 h; May–July 2000: 3 visits, 13.5 h; May–July 2001: 3 visits, 6.6 h; June–July 2002: 2 visits, 4.3 h; total search effort: 32 visits, 96.1 h). Furthermore, toad sightings in the 1970s were incidental to searches for garter snakes (*Thamnophis* spp.), whereas the searches in 1997–2002 were focused on amphibians, particularly *B. boreas*. Egg masses and larvae of the northwestern salamander (*Ambystoma gracile*), Pacific treefrog (*Hyla regilla*), and red-legged frog (*Rana aurora*) were common in 1997–2002, and adult *H. regilla* and *R. aurora* were seen frequently.

Weeks Lake (0.4 km^2 surface area) is the main water source for Jordan Meadows and was probably the primary reproductive site for the Jordan Meadows *B. boreas* population. In 1971, Oliver (1973) observed "several dozen" amplexing pairs of *B. boreas* in Weeks Lake. This lake has been stocked with about 1000 rainbow trout (*Oncorhynchus mykiss*) each year since 1984 (L. Friis, pers. comm.).

From 1997 to 2002, we searched the entire shoreline of Weeks Lake by boat on 22 separate occasions (total search time: 14.6 h). We scanned logs and the water for adult toads, and looked for tadpoles in shallow water. No *B. boreas* were seen, but other amphibians were common, especially the rough-skinned newt (*Taricha granulosa*) and *R. aurora*. Also, when conditions appeared to be favorable for toad activity, we searched along logging roads in the vicinity of Weeks Lake by motor vehicle on three nights in 1998 and one night each in 1999 and 2002 (total search time: 8.03 h). Again, no toads were seen, but other amphibians were common. In contrast, toads were routinely found using this method at another site 15 km east of Jordan Meadows (TMD, unpubl. data).

Because *B. boreas* is likely to exhibit dramatic year-to-year population fluctuations typical of r-selected species, it is important to continue to monitor Jordan Meadows to distinguish between a true local extinction and a temporary decline due to routine natural population fluctuations. Despite this caveat, our searches in Jordan Meadows suggest that recovery of this population is highly unlikely without recolonization and there are no known source populations. We do not know whether this extinction occurred because of adult mortality, failure of recruitment, or both, so it is difficult to assign causation. However, terrestrial habitat loss, road mortality, acid precipitation and chemical pollution are unlikely causes because the area has experienced little disturbance until recently. The introduction of exotic pathogens, either as a consequence of the introduction of rainbow trout to Weeks Lake or other human activities, is a more likely explanation.

Salmonid species probably are not responsible for declines of toad populations directly because *B. boreas* tadpoles are unpalatable to them (Drost and Fellers 1996; Kiesecker et al. 1996). However, these fish are highly susceptible to an oomycete pathogen, *Saprolegnia* spp., which can be introduced into lakes and ponds during fish stocking (Kiesecker and Blaustein 1997). The pathogen can either be reintroduced with each stocking or can become established as the result of a single stocking event. Infection of toad eggs and developing embryos by *Saprolegnia* spp. can cause significant embryo mortality (Blaustein et al. 1994b; Kiesecker and Blaustein 1997; Kiesecker et al. 2001b). The infection rate is increased by higher levels of UV radiation, to which *B. boreas* eggs are susceptible (Blaustein et al. 1994a,b; Kiesecker and Blaustein 1995; Kiesecker et al. 2001a). There are no other exotic vertebrate species known from this area, so synergistic effects as the result of multiple exotic species are unlikely to have occurred (e.g., Kiesecker and Blaustein 1998). Avoidance of introduced fish by tadpoles could have some negative effects on tadpole growth and development, although such behavior in *B. boreas* has not been investigated systematically. However, even if avoidance behavior does occur, it is unlikely to result in significant mortality or decreased growth rates because the preferred tadpole microhabitat is in shallow shoreline areas devoid of fish (TMD, pers. obs.).

Another possible cause of the extinction at Jordan Meadows is the introduction of bacterial or fungal diseases into the adult segment of the population. Populations of *B. boreas* in Colorado are thought to have disappeared as the result of infection with *Aeromonas hydrophila*, the bacterium that causes red-leg disease (Carey 1993). Other closely related species of *Bufo* are subject to a variety of fatal fungal infections, some of which have only recently been identified (Berger et al. 1998; Carey 2000; Carey et al. 1999; Taylor et al. 1999a,b,c,d). However, there is no direct evidence of any epidemic disease at Jordan Meadows, and whether or not such an epidemic occurred at this site is unknown.

The extinction at Jordan Meadows may be part of an overall decline of *B. boreas* on Vancouver Island. From 1995 to 1999, TMD failed to find *B. boreas* in lakes near Victoria, British Columbia for which there are historical museum specimens. Similarly, extensive amphibian surveys of lakes in the greater Victoria region in 1998–1999 failed to detect *B. boreas* (P. Govindarajulu, pers. comm.). Individual toads, dispersing metamorphs, and small schools of tadpoles were found in the Greater Victoria Watershed (GVW) in 1997–1999, 30 km NW of Victoria near Sooke Lake (48°34'N, 123°40'W), but GVW employees recall much denser breeding aggregations in the past.

Given the decline of this species in the southern part of its range, these observations from Vancouver Island highlight the need to assess and routinely monitor extant, apparently robust, populations of *B. boreas*. Although *B. boreas* is common at many locations in British Columbia, we have few data on the location of populations, their spatial distribution, or the numbers of individuals within populations. Without this information we are unlikely to detect population trends of *B. boreas*, or to identify the causes of local or regional extinctions.

Acknowledgments.—Steve Mitchell and Linda Gregory helped on searches in 1975–1979. We thank Robyn Kidd and Jeannine Caldbeck for their able assistance in the field in 1997–1999. Jovanna Richards, Logan Caldbeck, Aziza Cooper, Colleen Kasting, Kristiina Ovaska, and Purnima Govindarajulu also helped search Jordan Meadows in 1997–2002. Financial support for this project came from a grant to P. T. Gregory from Forest Renewal BC (HQ96142-RE).

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 34, Number 1 (March 2003).

CAUDATA

AMBYSTOMA GRACILE (Northwestern Salamander). **EGG PREDATION**. Northwestern salamanders (*Ambystoma gracile*) share breeding ponds with roughskin newts (*Taricha granulosa*) throughout their ranges in the Pacific Northwest, USA (Nussbaum et al. 1983. Amphibians and Reptiles of the Pacific Northwest. Univ. Idaho Press, Moscow. 353 pp.). *Taricha granulosa* and closely related California newts (*T. torosa*) are known to prey extensively on aquatic amphibian eggs, including those of conspecifics, foothill yellow-legged frog (*Rana boylii*), and Pacific treefrog (*Pseudacris regilla*) (White 1977. Northwest Sci. 51:114–118; Evenden 1948. Copeia 1948:219–220; Kats et al. 1992. Herpetol. Rev. 23:7–8). However, to my knowledge there are no published observations of field predation by *Taricha* on *A. gracile* eggs, nor reports of *A. gracile* eggs in *Taricha* stomach contents. Herein, I report a field observation of attempted egg predation by

T. granulosa on an *A. gracile* egg mass in the Willamette Valley, Oregon.

On 28 Feb 2002, I observed a mature male *T. granulosa* (ca. 65 mm SVL, 155 mm TL) swimming around an *A. gracile* egg mass in a semi-permanent pond on the W. L. Finley National Wildlife Refuge, 15 km S of Corvallis. The egg mass was an elongated globe ca. 7 cm diam x 13 cm height attached to a submerged spikerush (*Eleocharis* sp.) in ca. 60 cm of water, which is a typical oviposition site for *A. gracile* in this region. During 15 min of observation, the *T. granulosa* repeatedly propelled itself against the egg mass nose-first, continually adjusting its location around the periphery of the mass. I did not observe the *T. granulosa* gleaning items off the egg mass surface, and it did not appear affected by the presence of the observer. The *T. granulosa* was observed swimming away from the egg mass after all apparent attempts to penetrate the mass failed.

The heavy gelatinous matrix of *A. gracile* egg masses is known to allow embryos to survive exposure to air associated with receding water levels (Marco and Blaustein 1998. Herpetol. J. 8:207–211). These field observations suggest that an additional benefit of the heavy gelatinous matrix of *A. gracile* egg masses may offer protection from their oophagous pond associate, *T. granulosa*.

This study was funded by the USEPA as part of an interagency agreement between the Environmental Protection Agency and the USGS Biological Resources Division. Reviews by R. B. Bury and R. Hoffman improved this manuscript.

AMBYSTOMA MACULATUM (Spotted Salamander) and ***RANA SYLVATICA*** (Wood Frog). **HABITAT**. Regular extinction and recolonization in well-defined habitat patches, small relative to a matrix of lesser quality, are distinguishing characteristics of metapopulations (Hanski 1997. *In* Tilmand and Kareiva [eds.], Spatial Ecology: The Role of Space in Population Dynamics and Interspecific Interactions, pp. 21–45. Monographs in Population Biology 30, Princeton, New Jersey). For vernal pool-breeding amphibians, such as *Rana sylvatica* and *Ambystoma maculatum*, the patch consists of the breeding pool itself and the surrounding forest. These appear to be rarely unoccupied (Marsh and Trenham 2001. Cons. Biol. 15:40–49). We report on what seems to be an empty patch: a peninsular area with apparently suitable upland, several pools having optimal hydroperiod, and no evidence of breeding by wood frogs or spotted salamanders. The neighboring mainland has almost 90% pool occupancy and 100% occupancy of all optimal hydroperiod pools randomly surveyed. For comparison we describe a similar peninsular land mass farther north along the coast that does maintain breeding populations of these two species.

Two land masses connected to the mainland by causeways in coastal Maine have, by chance, been included in intensive studies of pool-breeding amphibian species: Biddeford Pool ("the Pool") (N43°26.76', W70°20.67), and Sears Island (N44°26.66', W68° 52.88'). The land masses are remarkably similar in size and connection to the mainland. Biddeford Pool (100 ha) is 1.4 km from the mainland. Sears Island (380 ha) is 0.80 km from the mainland. Sears Island was historically connected to the mainland by a sandbar that emerged twice daily at mid to low tide. A causeway and paved road were built in 1984. Biddeford Pool has a causeway of dune and marsh on which a road was recorded in 1803. It was improved in the 1920s and now is paved, connecting a year-round human community to the mainland. The Pool was settled in the 1600s. Prior to the 1930s Sears Island was used for timber harvesting and grazing, and has been largely uninhabited since then. The most significant difference between the two land masses for amphibian population dynamics appears to be the greater historical and current human use of the Pool.

Evidence collected during the spring and summer of 2002 strongly indicates that Biddeford Pool has no breeding by wood frogs or spotted salamanders, even though it has at least four suitable breeding sites and about 20 ha of the forest is undeveloped. The Pool does support breeding by green frogs (*Rana clamitans*). Occupancy was determined by multiple searches for egg masses and breeding animals, and larval trapping using minnow traps, April–August.

Ninety-three randomly selected vernal pools surveyed on the mainland adjacent to Biddeford Pool revealed that 88% of them were used for breeding. Those not used were at the shortest end of the hydroperiod—small, shallow pools (R. Baldwin, unpubl. data). However, 4 pools of the 6 identified by 1:12000 aerial photo interpretation on Biddeford Pool were visited 4 times during the season, from egg-laying to metamorphosis, and only breeding green frogs were detected, indicating that the land mass is devoid of wood frogs and spotted salamanders. The Pool pools were long-hydroperiod temporary pools (mean 140 days from egg laying). On the mainland the density of wood frog (Pearson's $r = .269$) and spotted salamander ($r = .507$) egg masses increased with hydroperiod ($N = 93$, $\alpha = .05$). Based on these mainland trends, if these animals were present on the Pool, one would expect them to be breeding in the pools surveyed.

In contrast, Sears Island maintains significant breeding populations of wood frogs and spotted salamanders, as well as green frogs. Amphibian sampling was conducted at three created pools on the island from 1999 to 2002 using 100% enclosure drift-fences and pitfall traps. Adults of all three species bred in each pool, with thousands of wood frog and hundreds of green frog and spotted salamander juveniles produced in most years (D. Vasconcelos, unpubl. data). A survey in 1975 documented the pre-causeway presence of wood frogs and spotted salamanders on the island.

In conclusion, it appears that there is an empty patch for pool-breeding amphibians on the coast of Maine—Biddeford Pool. However, given the presence of pool-breeding amphibians on Sears Island, a land mass of similar size and orientation to the mainland, it seems unlikely that unoccupied patches are a common occurrence. All pools with optimal hydroperiod in the sample on the mainland adjacent to the Pool are used intensively for breeding by wood frogs and spotted salamanders. It seems that the same would be true in the Pool, if the area were occupied. It is not surprising that the animals have been unable to colonize or recolonize the patch by walking down a busy road with ocean and bay on either side. However, the mainland is fully occupied and,

as Sears Island shows, similarly isolated land masses can and do have breeding populations.

PLETHODON CINEREUS (Eastern Red-backed Salamander). **CANNIBALISM**. It has been hypothesized that the risk of adult cannibalism of juveniles is an important force affecting the socioecology of some plethodontid species (Jaeger and Forester 1993. Herpetologica 49:163–175; Camp and Lee 1996. Copeia 1996:78–84; Jaeger et al. 1995. Ecology 76:533–543). However, evidence of cannibalism by plethodontids is limited, particularly in wild populations. It is hypothesized that juvenile red-backed salamanders, *Plethodon cinereus*, reside within the territories of related adults (presumably their parents) in part to reduce the risk of cannibalism from other adults (Jaeger and Forester 1993, *op. cit*; Jaeger et al. 1995, *op. cit.*). Adult cannibalism of juvenile *P. cinereus* has been reported in staged laboratory encounters (Bachmann 1984. Herpetologica 40:436–443; Wareing 1997. Honor's Thesis, State Univ. New York at Binghamton, Binghamton, New York); however, in published studies that summarized thousands of *P. cinereus* diets there is not a single report of cannibalism. Prior to this report, the lead author had sampled thousands of adult *P. cinereus* diets from 20 sites in New York and Pennsylvania, through all seasons, and under a variety of conditions, and never found a single event of cannibalism.

On 9 May 2001, within 24 h of rain, we conducted a routine survey of artificial coverboards at a long-term mark-recapture study site in Syracuse, New York. During the survey we collected diet samples from 52 *P. cinereus* by stomach flushing (*sensu* Fraser 1976. Ecology 57:459–471). We recovered a juvenile *P. cinereus* from the stomach of an adult male conspecific. The juvenile was a striped morph 11 mm in length between the fore and hind limbs (could not determine SVL because of state of digestion), which indicates the juvenile was a young of year that hatched in August 2000. The head of the juvenile was almost completely digested, and the forelimbs were partially digested with all the skin gone. From mid-trunk posteriorly the animal was slightly digested with most of the skin intact and the stripe clearly visible except the juvenile's tail was detached and well digested. This suggests that the male attacked once, causing the juvenile's tail to autotomize. After the male consumed the tail, he attacked the juvenile a second time, apparently toward the head, and swallowed the juvenile headfirst.

The male that consumed the juvenile was a lead morph, 39 mm SVL, reproductively active, and a recurring resident under the coverboard. We captured him under the same board on 18 April, 26 April, 9 May, and 27 July 2001. On 9 May, the day we recovered the cannibalized juvenile from the male, we also found another *P. cinereus* young of year and a 35 mm SVL, immature *P. cinereus* under the same coverboard. In addition to the juvenile *P. cinereus*, the male's stomach contained a centipede (1.46 x 0.67 mm), an isopod (1.83 x 1.28 mm), a small dipteran (1.55 x 1.01 mm), and part of an earthworm (4.66 x 0.94 mm). The number and volume of prey in the male's diet was normal to above average (Maerz 2000. Ph.D. Diss., State Univ. New York at Binghamton, Binghamton, New York). Based on the amount of other prey in the male's stomach and that the sample was collected within 24 h of rain when access to prey is generally not limited for *P. cinereus* (Jaeger 1980. Oecologia 44:335–341), it is unlikely that the male was food-limited at the time he cannibalized the juvenile.

Our observation of adult *P. cinereus* cannibalism of a juvenile in a wild population is the first such observation of which we are aware. Because the diets of *P. cinereus* have been studied extensively, it is unlikely that the rarity of cases of cannibalism in wild populations is the result of limited observation. Rather, it is likely that behavioral adaptations reduce the real occurrence of cannibalism in the wild. Adult *P. cinereus* can identify (probably chemically) and avoid cannibalizing their own offspring (Jaeger et al. 1995, *op. cit.*; Waering 1997, *op. cit.*; Wareing 1998. Master's Thesis, State Univ. New York at Binghamton, Binghamton, New York), and some juvenile *P. cinereus* can use chemical cues to avoid unrelated adults and their territories (Wareing 1997, *op. cit.*; Forester and Anders 2000. *In* Bruce et al. [eds.], The Biology of Plethodontid Salamanders, pp. 407–416, Kluwer Academic/Plenum Publishers, New York). Our observation shows that cannibalism does occur in wild *P. cinereus* populations, and, though such observations are rare, when considered in the context of laboratory studies, supports the hypothesis that cannibalism is a force shaping *P. cinereus* social behaviors.

Submitted by **JOHN C. MAERZ** and **JEREMIAH M. KARUZAS**, Department of Natural Resources, Cornell University, Ithaca, New York 14853-3001, USA; e-mail (JCM): jcm63@cornell.edu.

PLETHODON ELONGATUS (Del Norte Salamander). **FEMALE-FEMALE AGGRESSION**. Behavioral aggression appears to be widespread among terrestrial plethodontid salamanders (Jaeger and Forester 1993. Herpetologica 49:163–175; Maerz and Madison 2000. *In* Bruce et al. [eds.], The Biology of Plethodontid Salamanders, pp. 395–405. Kluwer Academic/Plenum Publishers, New York), however this behavior has not been reported for *Plethodon elongatus*. In this paper we report a field observation of two *P. elongatus* found under an 18 cm rock; the two salamanders ("A" and "B") were twisted around and biting one another. Animal A was biting animal B's tail, while in turn B was biting A's trunk at midbody. This observation was made on 5 Nov 2000 under weather conditions optimal for surface activity (9.5°C air temp, 10°C soil temp, and 82% relative humidity). Both individuals appeared to be adult females (by their short and swollen tails, swollen bodies, and rounded snouts) and both released one another after being disturbed. Closer examination revealed fresh, non-lethal, surface wounds at the bite locations on both animals. This observation of aggressive biting in *P. elongatus* occurred within the courtship season for this species and is consistent with the period of increased aggressiveness seen in *P. cinereus* (Livezey 1959. Herpetologica 15:41–42; Stebbins 1962. Amphibians of Western North America. Univ. California Press, Berkley and Los Angeles, California. 539 pp.; Welsh and Lind 1992. *In* McCullough and Barrett [eds.], Wildlife 2000, pp. 419–437. Elsevier Applied Science, New York).

ANURA

ACRIS CREPITANS BLANCHARDI (Blanchard's Cricket Frog). **BEHAVIOR**. *Acris crepitans blanchardi* is a common inhabitant of permanent bodies of water in the midwestern USA where it is associated with many terrestrial ambush predators such as bullfrogs and leopard frogs and aquatic predators such as fish. During early February 2002 in a non-farm pond near Pella, 45 miles SE of Des Moines, Iowa, I observed 3 individual *A. c. blanchardi* leap from hidden basking sites into 10–11°C water containing much recently shed and floating cattail (*Typha*) litter. Each frog initially landed on a piece of cattail litter, gradually sliding off during shoreline wave action and then floating freely. The frogs assumed a rigid body posture with knees held distally. Air bubbles adhered to each frog's dorsal bumps making each buoyant. Over a time span of ca. 5 minutes the bubbles gradually detached from the frogs. Each frog remained static as it sank, becoming briefly active on contact with submerged spikerush (*Eleocharis*). Frogs grasped the spikerush and remained static for ca. 20 minutes. Cricket frogs away from cattail litter dove directly to the bottom and clasped vegetation, remaining static for 17 to 23 minutes. Neither of these responses matches the shoreline orientation escape strategy as it is described for *A. crepitans* (Stebbins and Cohen. 1995. A Natural History of Amphibians. Princeton University Press, Princeton, New Jersey). The floating cryptic and direct diving behaviors were no longer seen by spring when all cattail litter was submerged and decaying, and when water temperatures reached 18°C. By that time all cricket frogs followed shoreline orientation strategy. The floating behavior appears to be associated with cool water temperatures and the presence of floating cattail litter.

Submitted by **STEPHEN R. JOHNSON**, Division of Health and Life Sciences, William Penn University, Oskaloosa, Iowa 52577-1799, USA.

ATELOPUS VARIUS (Harlequin Frog). **FUNGAL INFECTION.** The chytrid fungus *Batrachochitryium dendrobatidis* (Longcore and Nichols 1999. Mycologia 91:219–227), which affects the amphibian integument, has been associated with mass mortality in amphibian populations around the world (Berger et al. 1998. Proc. Natl. Acad. Sci. USA 95:9031–9036). Previous studies have found the fungus in tissues of *Atelopus* specimens collected in Panama (Lips 1999. Cons. Biol. 13:117–125), close to the Costa Rican border.

I examined specimens of *Atelopus varius* collected in Costa Rica from the Museum of Zoology at the University of Costa Rica. This species was previously widely distributed in Costa Rica, and it is well represented in the collection. It has been found infected in Panama, near the Costa Rican border, but the genus *Atelopus* (Bufonidae) now seems to be extinct in Costa Rica, where it was represented by four species (F. Bolaños, pers. comm.).

A small (ca. 1 cm^2) section of the skin in the groin area was removed, and processed for histological examination. After paraffin embedding, 3–4 mm sections were stained with hematoxylin and eosin. I examined 37 *A. varius* specimens, 14 collected between 1990 and 1996, 16 collected between 1986 and 1988, and 6 collected between 1979 and 1985. Two were infected. The first infected specimen was collected in 1992, already dead and dried out, in Rivas, San Isidro del General (UCR 11403) in the Talamanca Mountain Range. Many sporangia were present. This was the only specimen used in this study that was not alive when collected, and a second individual found in a nearby area was alive and clear of infection. These were the only specimens of *Atelopus varius* located on an expedition in the southern part of Costa Rica in 1992 (H. Pröhl, pers. comm.). The second individual is from San Ramón, Sarapiquí in the Cordillera Central Mountain Range (UCR 13303); it was collected in 1986. Only a small focal infection with few sporangia was present.

These data demonstrate that a potentially harmful fungus has been present in Costa Rican *Atelopus varius* since at least 1986. Further research will be needed to determine its possible impact on the local amphibian communities.

This study would not have been possible without the help of Idea Wild, Lee Berger, Maria del Carmen Obando, Joyce Longcore, Ana Victoria Lizano, Federico Bolaños, William Eberhard, and the Pathology Department of the National Children's Hospital of Costa Rica.

BUFO BUFO (Common Toad), ***ALYTES OBSTETRICANS*** (Midwife Toad), and ***RANA TEMPORARIA*** (Common Frog). **TREE CLIMBING**. No information on tree climbing activity in European anurans belonging to non-climbing families has been published. In July 2000 I observed numerous individuals utilize the tabular roots and low oak-trunks section of a centenary oakwood at the Natural Recreative Area of the Orgi Wood (42°57'N, 1°40'W), a protected area in Lizaso, Navarra province (Northern Spain). Since then I have collected more than 200 observations of this climbing behavior. *Bufo bufo* (N = 129) reaches 39 cm average height, maximum height recorded 197 cm; *Alytes obstetricans* (N = 66) 34 cm average height, maximum height 135 cm; *R. temporaria* (N = 9) 14 cm average height, maximum height 30 cm. The search for moisture on the epyphitic moss colonizing the tree bark may help explain this arboreal activity, as 79% of the anurans are observed on this moss or other substratum (AG, unpubl.). During the wet season (March to early June) the climbing activity observed was scarce. However, during the dry period (September–October), 72–82% of the climbing anurans observed were on the absorbent substrate. Thus, this climbing behavior could be related to searching for moisture when soil surface dries. Furthermore, these anurans repeatedly used the same trees, where they were recaptured over three months later. They are active all night, and at dawn seek shelter in burrows excavated at the base of the tree.

BUFO HOUSTONENSIS (Houston Toad). **GROWTH**. To determine behavior and development, emergent juvenile *Bufo*

houstonensis were followed during post-emergence at the Griffith League Ranch, Bastrop County, Texas, USA during the early summers of 2001 and 2002. The data for juveniles reported herein were collected from 12 March to 17 June 2001 and from 18 April to 25 June 2002. Observations were made in the morning (ca. 0700–1000 h), weather conditions were generally hot and/or humid with occasional rain.

Three *Bufo houstonensis* egg strands were each surrounded by three concentric aluminum fences placed 2 m, 5 m, and 8 m from the water line to capture juveniles upon emergence. Pitfall traps (2.5 L plastic paint buckets) were placed every 2 m along the fences. However, most juveniles were collected throughout the vegetation encircled by the traps rather than in the pitfall traps. Standard measurements were taken at the time of capture. Weight (WT) was measured to the nearest 0.001 g with an Acculab portable scale (model PP2060D). Snout–vent length (SVL), and head width (HW) were measured to the nearest 0.01 mm with 20 cm vernier calipers. Juvenile *B. houstonensis* were marked as a cohort, with each cohort receiving the same toe clip pattern. Juveniles were released 10 minutes after capture on the other side of the fence in which they were trapped in an attempt to determine movement and dispersal patterns.

Over the 68-day period, 336 juvenile Houston toads were captured, measured, and marked with 509 recaptures during the same period. Because of the cohort marking, individual identity could not be determined and, therefore it is unknown how many times an individual was recaptured.

Our data are compared with the results of work performed at the Houston Zoo (Quinn 1981. Final Report of the Captive Propagation/Release Program of the Houston Toad, *Bufo houstonensis*. Unpubl. Rept. to the U.S. Dept. of Interior, Fish and Wildlife Service, Office of Endangered Species. Submitted by Dept. of Herpetology, Houston Zoological Gardens. 51 pp.). Those data have not been published, however the authors have made those data available for these comparisons. Development of the Houston toad is poorly understood especially in the juvenile stage. Quinn and Mengden's (1983. Unpubl. ms.) summary of the measurement of Houston toad growth between 1981 and 1982 is one of the few data sets that can be compared in examining Houston toad development. However, those studies were performed in captive animals and thus may be only loosely comparable to results from the wild.

The span of 68 days was broken up into three periods to determine a more exact growth rate. SVL was determined to be an important indicator for growth. For the first period (18 April–10 May), SVL ranged from 7 to 14 mm (mean 8.6 mm; SD ± 1.28 mm). For the second period representing a second cohort emerging from 11 May to 2 June, SVL ranged from 8 to 13 mm (mean 9.8 mm; SD ± 1.59 mm). For the final cohort, during the period from 3 to 25 June, SVL ranged from 8 to 19 mm (mean 13.4 mm; SD ± 4.43 mm).

Captive juveniles (Quinn and Mengden, *op. cit.*) were not significantly larger than the wild-caught *B. houstonensis* reported herein. At age 1.8 months the captive juveniles measured 9–13 mm SVL (mean 11 mm; SD 1 mm); at 2.4 months 21–24 mm (mean 23 mm; SD 2 mm). Thus the growth rates determined in captivity (Quinn and Mengden, *op. cit.*) are very nearly those found for *B. houstonensis* in the wild.

Body weight was also determined to be an important indicator of growth and development. Quinn (1981) did not measure weight until 11.4 months of age, and therefore weight measurements cannot be compared between the two studies. However, in the wild for the first period, mean weight was 0.084 g (SD ± 0.048 g) and average growth rate was 0.004 g/day; for the second period average growth rate was 0.006 g/day with a mean weight of 0.113 g (SD ± 0.046 g). During the last period mean individual weight was 0.382 g (SD ± 0.321 g) with an average growth rate of 0.019 g/day. Considerable variation was found among individuals over the time period for both size and weight within a cohort.

Quinn (1981) determined that growth was most rapid during the first few weeks of life and then gradually declined as the toads reached adult size during the first year for males and second year for females. During the past two years, we have collected and observed juveniles during the first months of the year (Jan–Mar). This is important given the belief that breeding maturation can occur during the first year of life. Such parameters are critical for efficient population modeling of the species.

We thank H. Quinn, G. Mengen, staff of the Houston Zoo, and J. R. Dixon for assistance in obtaining background information from captivity. We thank M. Gaston, T. Swannack, and T.L. Ahlbrandt for assistance in the field. This work was supported, in part, by a collaborative grant to MRJF from the United States Fish and Wildlife Service, Texas Parks and Wildlife Department, Southwest Texas State University, and the Capital Area Council-Boy Scouts of America. Additional funding was provided by ALCOA, Inc.

BUFO OCELLATUS (Ocellated Toad). **DIET.** *Bufo ocellatus* occurs in Minas Gerais, Mato Grosso, Goiás, and Pará in Brazil (Frost 1985. Amphibian Species of the World. Allen Press, Inc. and Assoc. Systematics Collections. Lawrence, Kansas. 732 pp.). Aspects of the trophic ecology of this species have been little investigated in natural populations from central Brazil. We analyzed the stomach contents of 13 specimens (43.3 ± 4.3 mm SVL) collected during the Corumbá I Hydroelectric Power Plant reservoir formation (17°59'S, 48°31'W), Caldas Novas municipality, Goiás State, between Sept 1996 and April 1997. Although isolation of populations, and therefore variation in food resource availability may occur during reservoir formation (Paiva 1999. Conservação da Fauna Brasileira. Ed. Interciência. Rio de Janeiro. 260 pp.), these analyses indicated the most frequently taken prey items were Coleoptera (N = 16; 3.6%), Hemiptera (N = 2; 0.45%), Hymenoptera (N = 298; 67.1%, Formicidae), Isoptera (N = 124; 27.9%), and miscellaneous (N = 3; 0.7% plant material; N = 1; 0.2% stones).

The volume of the items were: Coleoptera 418.4 mm^3, Hemiptera 17.8 mm^3, Hymenoptera (ants) 7045 mm^3 and Isoptera 4893.3 mm^3. Coleoptera were present in nine stomachs, Hemiptera in one, Hymenoptera (ants) in thirteen, Isoptera in five, plant matter in three, and stones in one. The diet of the 13 *B. ocellatus* was dominated numerically and volumetrically by Hymenoptera (Formicidae).

BUFO PARACNEMIS (Cururu Toad). **DIET.** Although aspects of trophic ecology of *Bufo paracnemis* were discussed by some authors (Guix 1993. Rev. Esp. Herpetol. 7:65–73; Lajmanovich 1995. Alytes 13:87–103; Dure and Kehr 1996. Herpetol. Rev. 27:138), in natural populations of Cerrado region, Central Brazil, the diet has been little investigated. Stomach contents of 24 specimens (males: N = 5, 134.5 ± 5.6 mm SVL; females: N = 19, 114.25 ± 10.75 mm SVL,) collected between September 1996 and April 1997during the Corumbá I Hydroelectric Power Plant reservoir formation (17°59'S, 48°31'W), Caldas Novas municipality, Goiás State, were analyzed. The diet was represented most numerically and volumetrically by Formicidae. Table 1 summarizes data collected during this study.

DERMATONOTUS MUELLERI (Mueller's Narrow-mouthed Frog). **DIET.** *Dermatonotus muelleri* has a wide distribution in northern Argentina, Paraguay, southeastern Bolívia, and southeastern, central, and northeastern Brazil, from Maranhão State to São Paulo State (Frost 1985. Amphibian Species of the World. Allen Press, Inc. and Assoc. Systematics Collections. Lawrence, Kansas. 732 pp.; Silva et al. 2002. Herpetol. Rev. 33:144). We investigated the diet of 27 specimens (males: N = 15, 56.9 ± 4.0 mm SVL; females: N = 12, 64.1 ± 10.9 mm SVL,) collected 23–25 October 2000, in Minaçu municipality (13°34'32"S, 48° 06'94"W), Goiás State, Central Brazil. The diet was composed of Hymenoptera and Isoptera; the following termites were identified: *Nasutitermes kemneri*, *Constrictotermes cyphergaster*, *Cornitermes snederi*, *Grigiotermes* sp., and *Ruptitermes* sp. Although other authors have reported ants and termites in the diet of this species (Cei 1980. Amphibians of Argentina. Monitore Zoologico Italiano [NS] Monog. 2:609; Norman and Naylor 1994. Amphibians and reptiles of Chaco Paraguayo. Ed. San José, 1:281), this is the first report of the diet from populations of the Cerrado region in central Brazil.

Submitted by **WILIAN VAZ-SILVA**, **HÉLDER LÚCIO RODRIGUES SILVA**, and **NELSON JORGE DA SILVA JUNIOR**, Laboratório de Herpetologia, Centro de Estudos e Pesquisas Biológicas, Universidade Católica de Goiás, Ave. Universitária 1440, Setor Universitário, 74.210-010, Goiânia, Goiás, Brazil; e-mail (WV): wilianvaz@uol.com.br.

ELEUTHERODACTYLUS NOBLEI (NCN). **REPRODUCTION AND PARENTAL CARE.** The genus *Eleutherodactylus* contains ca. 600 species of New World frogs that comprise a substantial component of many neotropical herpetofaunas (Savage 2002. The Amphibians and Reptiles of Costa Rica. Univ. Chicago Press, Chicago, Illinois, 934 pp.). Although data on reproduction are lacking for most species, all species for which data are available are characterized by terrestrially-deposited eggs and direct development of the embryos. Most species exhibit parental care in the form of nest attendance by either the female or male. Few data on reproduction are available for members of the exclusively mainland subgenus *Craugastor*, and reproduction and parental care have not been described for any of the 11 species in the *gollmeri* species group. *Eleutherodactylus noblei* belongs to the subgenus *Craugastor*, and is a member of the *gollmeri* species group. Herein we describe a clutch of eggs, nest site, and presence of parental care in *E. noblei* from a lowland tropical forest in northeastern Costa Rica.

On 03 May 2000, we found one adult female *E. noblei* (46.6 mm SVL) sitting on a clutch of 29 eggs at La Selva Biological Station, Heredia Province, Costa Rica. The nest was deposited beneath leaf litter between the buttresses of a large tree. There was no nesting cavity, but the eggs were located in a shallow depression (< 10 mm deep). Although we witnessed no direct parental behaviors, *E. noblei* is relatively uncommon at this site, and direct association of a female with embryos of such a late

developmental stage strongly indicates nest attendance.

The eggs measured ca. 5 mm in diameter and were yellowish-cream below. We used a staging table for development of embryos in *E. coqui* (Townsend and Stewart 1985. Copeia 1985:423–436) in order to estimate developmental stage of embryos. Although this staging table is specific to *E. coqui*, we believe it may be useful to provide a rough estimate of developmental stage in *E. noblei*. We estimated that the eggs were at Stage 5– 6 of 15 stages: the embryos had evident front and hind limbs, conspicuous eyes, and were observed moving within the eggs.

We collected four eggs from the clutch and placed them in a plastic container filled with leaf litter in the laboratory to observe development. We monitored the remaining eggs in the field periodically, but never saw the female at the nest site again, possibly because of our disturbance of the nest site. The remaining eggs in the field were depredated between 4–7 May. One of the four eggs in the laboratory began to mold by 13 May and was removed; the remaining three eggs hatched on 22 May. Only one hatchling was measured (9.1 mm SVL). Given the advanced developmental stage in which the eggs were found, development time for this species must be considerably longer than 19 days.

While there is considerable variation in the sex of the parent providing parental care throughout this genus, nest attendance by the female is typical for the subgenus *Craugastor* (Townsend 1996. *In* Powell and Henderson [eds.], Contributions to West Indian Herpetology, a Tribute to Albert Schwartz, pp. 229–239. SSAR Contrib. Herpetol. Vol. 12. Ithaca, New York, 457 pp.). The data provided herein for *E. noblei* suggest that reproduction in the *gollmeri* species group may be similar to other species within the subgenus *Craugastor*.

HYLA VERSICOLOR (Gray Treefrog). **BEHAVIOR.** The Chinese tallowtree, *Triadica sebifera* (Euphorbiaceae), is an introduced noxious weed (USDA, NRCS. 2002. The PLANTS database, ver. 3.5 [http:plants.usda.gov]; National Plant Data Center, Baton Rouge, Louisiana) that has become extremely common in disturbed habitats and along the banks of waterways in Louisiana. It is a deciduous tree that reaches > 10 m in height, and often contains tree-holes that are produced as the branches rot. The branches are very porous, and dead branches are apparently particularly vulnerable to fungi and insects. Herein I describe the use of these cavities and aggregate behavior in *Hyla versicolor*, neither of which has been previously reported to my knowledge.

On 25 January 1998 (1400 h), while removing a Chinese tallowtree (75 cm diam at breast height [DBH]), I discovered three *H. versicolor* within a tree-hole cavity (ca. 10 cc) in a 15 cm diam branch. The branch was 3 m above the ground before the tree was felled. The tree was located 5 km W of Hammond, Louisiana (Tangipahoa Parish). The temperature was 13°C, weather was overcast with a 10 km/h north wind, and all frogs were apparently in good condition, nestled on top of one another in the bottom of the cavity.

In a similar situation involving tree removal on 10 January 2002 (1100 h, weather clear, wind calm, temp. 16°C), 2 km E of Ville Platte, Louisiana (Evangeline Parish), I discovered four *H. versicolor* in a tree-hole cavity in the trunk of a Chinese tallowtree (85 cm diam DBH), 2.5 m above the ground. In this case, the frogs began emerging from the cavity once the tree was felled, and were also apparently in good condition.

These observations are significant as they document the use of an introduced tree species as microhabitat, as well as aggregate (potentially overwintering) behavior in *H. versicolor*. These tree-hole cavities may represent an introduced resource to treefrogs (and other cavity dwelling species), as tree-hole cavities may be generally limited in abundance, and shelter defense is widespread in anurans (Duellman and Trueb 1986. Biology of Amphibians. Johns Hopkins Univ. Press).

Submitted by **CLIFFORD L. FONTENOT, JR.**, Department of Biological Sciences, Southeastern Louisiana University, Hammond, Louisiana 70402, USA; e-mail: cfontenot@selu.edu.

LEPTODACTYLUS FALLAX (Mountain Chicken). **OPHIOPHAGY.** *Leptodactylus fallax* is one of the world's largest frog species. Adults commonly reach 190 mm SVL and often weigh in excess of 600 g. They are now found only on the West Indian islands of Dominica and Montserrat, though are believed to have occurred on Martinique, St. Kitts, Nevis, Antigua, and St. Lucia.

On 27 Aug 2001 at 2129 h during a population assessment of the mountain chicken in the Centre Hills of Montserrat, an adult female mountain chicken (175 mm SVL, 510 g) was caught consuming a Montserrat black racer *Alsophis antillensis manselli* (female; 650 mm TL, 75 g).

The frog was sitting, partially concealed in leaf litter, to one side of a trail through the forest. Dangling from its mouth was ca. 150 mm of snake tail. Upon capture, the frog immediately started to regurgitate its dead prey. The 500 mm of snake which had been inside the frog had presumably been there for some time, as the frog's digestive juices had reduced it to little more than a skeleton. The posterior portion not ingested remained largely intact, though it had started to decompose.

From what is known of the feeding behavior of *L. fallax* observed in captivity (pers. obs.), it is unlikely the racer was eaten dead. Most likely the frog pounced on movement in the leaf litter, seized the head of the snake and then started to ingest it. The stomach of the frog was unable to accommodate the entire length of the animal—hence the protruding tail. It is possible that the frog would have succeeded in ingesting the remaining portion of the snake, once the anterior part had been sufficiently digested.

There is one earlier report of *L. fallax* eating a snake. Brooks (1982. Biotropica 14:301–309), in his analysis of prey consumed by mountain chickens in Dominica, found a specimen that had eaten a blind snake, *Typhlops dominicana*. Unfortunately the size of the prey item was not recorded, although *T. dominicana* do not exceed 385 mm TL (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies. University of Florida Press, Gainesville). It is likely that other voracious anurans (e.g., *Ceratophrys ornata*, *Discodeles guppyi*, and *Rana catesbiana*) are regular predators of large prey, including snakes (Duellman and

Trueb 1986. Biology of Amphibians. The John Hopkins University Press, Baltimore). However, I cannot find any previous records of an anuran attempting to ingest such a large snake prey item as reported herein.

My thanks to the staff of the Forestry Department of Montserrat, in particular Calvin Fenton and Lloyd Martin, also to Siân Buley for constant help, advice, and knowledge during the fieldwork, and to Mark Stanley-Price and Anna Feistner for comments on the manuscript.

LEPTODACTYLUS LABYRINTHICUS (Labyrinth Frog). **DIET.** *Leptodactylus labyrinthicus* occurs in cerrados and caatingas of northern (Roraima), northeastern and central Brazil, coastal Venezuela, eastern Paraguay, and southeastern Brazil (Frost 1985. Amphibian Species of the World. Allen Press, Inc. and Assoc. Systematics Collections. Lawrence, Kansas. 732 pp.). Some aspects of the ecology of *L. labyrinthicus* were discussed by Cei (1980. Amphibians of Argentina. Monitore Zoologico Italiano [NS]. Monogr. 2, 609 pp.), but the diet has been little investigated in natural populations from Brazil. We analyzed the stomach contents of four specimens (male: 158 mm SVL, N = 1; females: 144.9 ± 14.7 mm SVL, N = 3) collected during the Corumbá I Hydroelectric Power Plant reservoir formation (17°59'S, 48°31'W), Caldas Novas municipality, Goiás State, between September 1996 and April 1997. Table 1 summarizes data collected during this study.

PHYSALAEMUS NATTERERI (NCN). **MALE-MALE COMBAT**: *Physalaemus nattereri* has a wide distribution in central and southeastern Brazil and Eastern Paraguay (Frost 2002. Amphibian Species of the World: An Online Reference.V2.20. American Museum of Natural History). Despite this wide distribution, little data are available concerning its behavior. Herein we describe agonistic interactions between two male *P. nattereri* in a temporary pond ca. 1 m deep and 4 m diameter at Patrocínio, Minas Gerais State, Brazil (1008 m elev.) (18°59'47" S, 40°48'13" W).

The observations took place during the night of 9 Oct 2001 when many species of anurans were vocalizing and *P. nattereri* were observed in amplexus. We observed two male *P. nattereri* from 1910 to 2005 h. The agonistic interactions followed these steps: while emitting an advertisement call male A moved to a stump and stood partially submersed in the water for ca. 10 min; male B, also emitting advertisement calls, approached male A but was expelled, this caused an increase in the call rate of male B; male A then moved to a small round hole under the stump and continued to emit advertisement calls; ca. 15 minutes later male B moved and sat next to the hole, emitting advertisement calls for 4 min, while male A remained calling; male B entered into the hole and sat beside male A; both males began an acoustic duel by alternatively emitting advertisement calls; male A pushed male B out of the hole, but male B returned and was pushed under the water where it was held for ca. 20 seconds by male A; male B then emerged behind male A, which turned and again pushed male B away from the hole; male B persisted in trying to return to the hole but was once again pushed away; after a third attempt, male B finally left male A's territory and moved to the edge of the pond ca. 3 m from the stump where it resumed calling. During physical combat, both males emitted calls. After this agonistic encounter, observations continued for 30 minutes but additional interactions were not observed.

We thank Brandt Meio Ambiente and Programa de Bolsas de Iniciação Científica (PROBIC) of PUC Minas for the financial support, and Dr. Carlos Alberto Gonçalves Cruz and Henrique Wogel for suggestions and comments on the manuscript.

Submitted by **FILIPE MARCOS HORTA NUNES** (e-mail: fmocoto@hotmail.com), **VINICIUS BARBOSA DE ASSIS**, **BRANDT MEIO AMBIENTE**, and **LUCIANA BARRETO NASCIMENTO**, Museu de Ciências Naturais and Departamento de Ciências Biológicas/PUC Minas, 30535-610, Belo Horizonte, MG, Brazil (e-mail: luna@pucminas.br).

PHYSALAEMUS RIOGRANDENSIS (NCN). **DIET.** In Argentina, *Physalaemus riograndensis* occurs in Corrientes, Entre Ríos, and Santa Fe provinces, and otherwise ranges from southern Brazil to Uruguay, inhabiting marshy, hygrophilous wood and wet pasture lands. This frog is often found during daylight hours floating on the water's surface or in vegetation beside lagoons at night. Although select aspects of the ecology of this leptodactylid were discussed by Gallardo y Varela de Olmedo (1992. Fauna de agua dulce de la República Argentina. 1:116) and Langone (1994. Museo Damaso Antonio Larrañaga, N° 5:123), the diet has not been described.

Thirteen individuals were collected in a pristine reserve "Parque General San Martín" (31°40'S; 60°30'W, Entre Ríos province, Argentina), (7 males, mean = 20.37 mm ± 0.09; and 6 females, mean = 19.98 mm ± 0.14 SVL). The individuals were captured with "wet pitfall traps" between the first week of December 1999 and 14 March 2000 following the Vogt and Hine (1982) criterion.

Table 1 summarizes dietary data of *P. riograndensis*; 110 prey items belonging 10 prey categories were identified (7 Insecta, 2 Arachnida and 1 Miriapoda items). The minimum sample (H_k) calculated was 11 individuals, and the trophic diversity (H) was 1.48 (± 0.38). The most frequently taken prey items were arachnids (N = 40; 36.39 %), followed by hymenopterans (N = 20; 18.23 %), collembola (N = 17; 15.45 %), and coleopterans (N = 16; 14.54%). The values of the index of relative importance (IRI) revealed that the main diet of *P. riograndensis* is made up of arachnids (IRI = 4038) and hymenopterans (IRI = 2564). The results showed that *P. riograndensis* is a non-specialised "sit-and-wait" predator.

We thank Norberto Muzzachiodi for his assistance in the field survey.

PSEUDACRIS CRUCIFER (Spring Peeper). Predation. General surveys of the herpetofauna of the upper Midwest (e.g., Vogt 1981. Natural History of Amphibians and Reptiles of Wisconsin, Milwaukee Public Museum, Milwaukee, Wisconsin; Oldfield and Moriarty 1994. Amphibians & Reptiles Native to Minnesota, University of Minnesota Press, Minneapolis, Minnesota) do not mention specific predators of spring peepers, although Harding (1997. Amphibians and Reptiles of the Great Lakes Region, University of Michigan Press, Ann Arbor, Michigan) stated that fish will eat them readily. On 20 April 2001, the remains of a *P. crucifer* were found in the gut of a brown trout (*Salmo trutta*), 21.9 cm in total length, collected by angling in Beaver Creek ca. 2 km upstream from its confluence with the Whitewater River, Winona Co., Minnesota (T108N, R10W, Sec 16). The creek is bordered by springfed marshes, where *P. crucifer* were calling on 20 April. Harding (op. cit.) suggested that the habit of spring peepers to breed in cool waters in early spring reduces contact with many potential predators. However, brown trout may be more likely than most other fish species to prey opportunistically on spring peepers because they actively feed in relatively cool temperatures.

RANA CATESBEIANA (Bullfrog) **PREDATION.** *Rana catesbeiana* is known to eat a variety of small vertebrates including snakes (Bury and Whelan 1984. Ecology and management of the bullfrog. U.S. Dept. Interior, Fish Wildl. Serv., Resource Publ (155):1-23, and references therein).

Table 1 provides data on bullfrogs from the San Mateo Canyon Wilderness Area on the upper portion of the San Mateo

TABLE 1. Bullfrog, *Rana catesbeiana*, and prey, *Thamnophis hammondii*, collected in Riverside County, California, during 2001.

Date collected	Bullfrog sex	Bullfrog mass (g)	Bullfrog SUL (mm)	Snake mass (g)	Snake SVL (mm)
20 June	female	402.1	140	35.2	501
24 July	—	154.7	108	3.38	220
24 July	female	223.5	130	2.97	197
22 Aug	male	51	86	2.82	185

Creek drainage, in the Cleveland National Forest, Riverside County, California (T7S, R5W) that contained *Thamnophis hammondii* in the stomach contents. The condition of the prey items collected on 20 June and 24 July suggested they had been recently consumed.

In the examination of the stomach contents of over 500 bullfrogs collected from three California drainages no other snake species was observed. While anecdotal information may exist on bullfrogs consuming native California snakes, to the best of our knowledge this report is the first repeated account of bullfrog consumption of the two-striped garter snake, *T. hammondii*, a species of special concern for the State of California.

RANA ZWEIFELI (Zweifel's Frog) **DIET**. On 11 May 2001 at 2045 h, in a pond in tropical low forest at Nuevo Urecho, Michoacan, Mexico (19°09'03"N, 101°47'17"W) at an elevation of 650 m, we observed *Rana zweifeli* (9.6 cm SVL) devouring a crab (Decapoda: *Pseudothelphusa dilatata*). Most amphibians are considered opportunistic feeders and their diet generally reflects food availability. The *R. zweifeli* and the crab were photographed, collected, and deposited in the Colección Nacional de Anfibios y Reptiles (CNAR; IBH-13761), and Colección Nacional de Crustaceos of the Instituto de Biología, Universidad Nacional Autónoma de México.

TESTUDINES

EMYDOIDEA BLANDINGII (Blanding's Turtle). **MATING BEHAVIOR**. This report documents *E. blandingii* mating behavior in New Hampshire, and notes variations in mating between New Hampshire *E. blandingii* and other populations. We recorded data on 24 *E. blandingii* (7 female, 16 male, 1 juvenile) within 5 wetland complexes in Rockingham and Strafford counties, New Hampshire. These complexes included freshwater marshes, scrub-shrub and forested wetlands, permanent open water, temporary wetlands, and riparian areas. Five radio-tagged *E. blandingii* (2 females, 3 males) were observed mating on 10 occasions. *Emydoidea blandingii* exhibit a mounting-type courtship display where almost all courtship motor patterns leading to successful copulation are performed during the mounting phase, with only a brief chase proceeding mounting (Baker and Gillingham 1983. Herpetologica 39:166–173; Bels and Crama 1994. Copeia 1994:676–684). We defined a mating occurrence when we observed a male mounted on a female in a plastron to carapace position with the claws and digits of the male grasping the carapacial margins of the female. Mating pairs were completely or partially submerged in water. Male carapacial emergence during mating was noted in 63% (2 not recorded) of the cases described here. Other studies describe mating pairs in union underwater (e.g., Graham and Doyle 1979. J. Herpetol. 13:125–127), but few studies mention partially emerged mating pairs. A photograph in Vogt (1981. Natural History of Reptiles and Amphibians of Wisconsin. Milwaukee Public Museum, Milwaukee, Wisconsin. 205 pp.) exemplifies male carapacial emergence in this species. In this study, the average substrate and water depth for mating pairs was 13 cm and 29 cm, respectively (range: substrate 3–34 cm; water 15–55 cm), and unconsolidated but firm organic substrates predominated. The significance of water and substrate depth as a factor in the initiation of courtship in this species is unknown but Baker and Gillingham (1983, *op. cit.*) describe obligatory breathing periods during courtship, and shallow water depths may facilitate respiration during mating.

Mating activity was observed within emergent marshes (N = 5), scrub-shrub wetlands with an emergent marsh component (N = 3), a forested wetland with an emergent marsh component (N = 1), and a pond (N = 1). A radio-tagged male observed mating on 5 November 2001 apparently entered dormancy soon after and overwintered at the site. *Emydoidea blandingii* have been shown to aggregate in overwintering sites in some populations (Ross and Anderson 1990. J. Herpetol. 24:6–12), and as a result chance meetings and mating opportunities may be enhanced.

Mating activity was observed throughout the day (range: 0930 h to 1830 h) from 18 June to 5 November with the following monthly distribution: June (1), July (1), August (3), October (4), and November (1). Ernst et al. (1994, Turtles of the United States and Canada, Smithsonian Institution Press, Washington, D.C.) note that field observations of mating are most common from March to July although *E. blandingii* mating activity has been recorded in every month from March to November. The potential importance of late season mating in the reproductive success of *E. blandingii* is unknown but may serve to increase mating oppotunities, especially in peripheral populations where chance encounters are decreased by small population size and discontinuity. Female *E. blandingii* can store viable sperm over the winter, and for up to three years after a mating (J. Harding, unpubl. data).

Emydoidea blandingii in this population were promiscuous. We observed a radio-tagged female with different partners in August and October, and a radio-tagged male with different partners in October and November. In addition, multiple mating was observed in the same mating pair at various times throughout the field season. For example, a radio-tagged pair was observed mating at two different times in October, and another pair was observed mating

in June, July, and August. Moreover, the male from the latter pair was observed mating in August with another female residing in a separate wetland.

This work was supported by the New Hampshire Fish and Game Department and the New Hampshire Department of Environmental Services with funds from the Environmental Protection Agency.

GLYPTEMYS INSCULPTA (North American Wood Turtle). **DIET**. It has been reported that *Glyptemys (=Clemmys) insculpta* is an opportunistic omnivore and consumes a wide variety of vegetative and animal materials. Recorded vegetative items in their diet include mushrooms, algae, mosses, grasses, violets (*Viola* spp.), cinquefoil (*Potentilla canadensis*), strawberry leaves (*Fragaria virginiana*), blackberries and raspberries (*Rubus* sp.), blueberries (*Vaccinium* sp.), greenbrier (*Smilax* sp.) and willow (*Salix* sp.) leaves, and sorrel, while animal items noted include earthworms, leeches, slugs, snails, insects, fishes (*Caprinus carpio* and *Castastomus commersoni,* probably as carrion), tadpoles, frogs (*Rana clamitans*), and newborn mice (Ernst 2001. Chelon. Cons. and Biol. 4:94–99; Farrell and Graham 1991. J. Herpetol. 25:1–9; Niederberger and Seidel 1999. Chelon. Cons. Biol. 3:414–418; Surface 1908. Zool. Div. Zool. Pennsylvania Dept. Agric. 6:105–196). Here we document additional food items not previously reported. All observations were made in the vicinity of a Delaware River tributary in Warren County, New Jersey, USA. On 1 August 2001, at 1148 h, we observed an adult male *G. insculpta* (CL = 198.5 mm) eating corn (*Zea mays*) in an agricultural field. The turtle had torn away the husk and was eating the corn directly off the cob. Fecal material collected from two additional *G. insculpta* contained corn, indicating that the former observation was not isolated. In the study area, the foraging activities of black bears (*Ursus americanus*) and beavers (*Castor canadensis*) in cornfields adjacent to *G. insculpta* riparian habitat appear to increase the accessibility of corn to the turtles. Black bears pull down large stands of mature corn while feeding, and beavers cut large numbers of mature corn stalks and drag them to the nearby stream. Numerous corncobs were observed along the stream bank and bottom during the late summer in 2000–2002.

On 6 July 2000, at 1145 h, we observed an adult male *G. insculpta* (CL = 210.5 mm) consume the stem and leaves of a 1 m tall milkweed plant (*Asclepias* sp.). Additionally, on 4 June 2002, at 1530 h, we observed a gravid female (CL = 174.7 mm) consume the stem of a young milkweed plant emerging in an agricultural field. The stems, leaves, and roots of *Asclepias* contain steroid glycosides and toxic resinous substances reported to be moderately to severely toxic for some herbivores (Aiello [ed.] 1998. The Merck Manual, 8th ed. Merck & Co., Inc., Whitehouse Station, New Jersey).

On 2 October 2001, at 1410 h, we observed a juvenile *G. insculpta* (CL = 153.5 mm) consuming the berries of a pokeweed plant (*Phytolacca americana*). This individual was foraging at the base of the plant and eating the fallen berries. The turtle's beak was covered with the berries' scarlet juice. All parts of the pokeweed plant contain oxalic acid and a saponin (phytolaccotoxin) which may cause death in domestic livestock (Aiello [ed.] 1998, *op. cit.*). Pokeweed is also consumed by the sympatric Eastern Box Turtle (*Terrapene carolina*), and passage of pokeweed seeds through the Box Turtle's digestive tract (and presumably that of *G. insculpta*) may increase the germination rates for this species (Braun and Brooks 1987. Amer. Midl. Nat. 117:312–318).

MACROCHELYS TEMMINCKII (Alligator Snapping Turtle). **REPRODUCTION.** We are aware of only one published observation of natural nesting by this species in Georgia, USA. Powders (1978. Copeia 1978:154–156) discovered a female completing a nest (clutch of 10 eggs) on 3 June 1975 30 m from Muckalee Creek (Flint River drainage) in Sumter Co. Additionally, Redmond (in Pritchard 1989. The Alligator Snapping Turtle: Biology and Conservation. Milwaukee Publ. Mus., Milwaukee, Wisconsin. 104 pp.) reported that slaughtered females from Terrell County (Flint River drainage) contained shelled eggs from 15 May to 15 June, and at least some captive females there nested in late May 1982. Here we report two additional observations of nesting in nature.

On 12 May 1999, Georgia Department of Natural Resources ranger Danny Bishop observed an alligator snapping turtle nesting in an open wildlife food plot ca. 70 m from Muckaloochee Creek (Flint River drainage), ca. 10 km N of Leesburg, Lee Co. Seven hatchlings were found emerging 26 August, but others may have emerged earlier or later. Photographs of the nesting female and resulting hatchlings were provided to JBJ.

On 24 April 2000, a hunter (G. Timmons) reported to DRJ the accidental excavation of an alligator snapping turtle nest from an open wildlife food plot situated ca. 30 m upslope from the Ochlockonee River, 1 km upstream of the confluence of Tired Creek, Grady Co. (30°44'31"N, 84°12'55"W). The site was ca. 7 km N of the Florida state line and 11 km N of the northernmost Florida nesting observed 10 May 1973 by Ewert (Ewert 1976. Herpetologica 32:150–156). The turtle had walked only 3 m into the food plot before nesting. The clutch of 42 eggs was salvaged and incubated. Forty eggs hatched 27 July–6 August, and all hatchlings (documented by color slide UF 134684, Florida Museum of Natural History Herpetology Dept. photographic archive) were released 24 August.

These new observations suggest that nesting in southernmost Georgia may begin nearly as early as in northern Florida (Ewert and Jackson 1994. Florida Game and Freshwater Fish Commission Nongame Wildl. Progr. Final Rpt. NG89-20), where reproduction has been much better studied, and that clutch sizes are comparable. Data summarized here also suggest that nesting occurs somewhat later as one moves only a small distance northward.

We thank Michael Ewert for reviewing a draft of the manuscript.

Submitted by **DALE R. JACKSON**, Florida Natural Areas

Inventory, 1018 Thomasville Road, Suite 200-C, Tallahassee, Florida 32303, USA (e-mail: djackson@fnai.org), and **JOHN B. JENSEN**, Georgia Department of Natural Resources, Nongame-Endangered Wildlife Program, 116 Rum Creek Drive, Forsyth, Georgia 31029, USA (e-mail: John_Jensen@dnr.state.ga.us).

PSEUDEMYS CONCINNA SUWANNIENSIS (Suwannee Cooter). **REPRODUCTION, LIFE SPAN.** Data on reproductive longevity are scant for many freshwater turtles, particularly those that normally lack visible growth annuli. Such is the case for the Suwannee Cooter, the largest North American emydid, whose reproductive biology was delineated by Jackson and Walker (1997. Bull. Florida Mus. Nat. Hist. 41:69–167) based on a six-year study at Wakulla Springs State Park (WSSP), Wakulla County, Florida. On 28 April and 30 June 1999, 28 June 2000, and 7 April and 29 June 2001, an attempt was made to recapture nesting female cooters that had been marked by shell-notching during 1988–1993 at WSSP (Jackson and Walker, *op cit.*). An additional observation from 18 May 2002 was provided by R. Franz. Eleven of 31 emergent females were confirmed as having first been observed nesting in 1988(4), 1989(4), 1990(2), or 1991(1). Minimum reproductive life spans ranged from 10 to 15 years. It is unknown how many years these females had nested prior to being marked. Given that minimum age to maturity is at least 10 years (Jackson and Walker, *op cit.*), all of the females were > 20 years old upon recapture. Growth rates of these females (plastron lengths, PL = 335–365 mm; carapace lengths, CL = 372–417 mm; carapace widths, CW = 277–301 mm; shell heights, SH = 143–165 mm; N = 10, all measurements maximal) were extremely low, with annual mean increases of 0.5 mm (PL), 0.8 mm (CL), 0.6 mm (CW), and 0.5 mm (SH).

I thank Carla McGowan, Dick Franz, and George Heinrich and his turtle workshop students for assisting with field work.

RHINOCLEMMYS RUBIDA (Mexican Spotted Wood Turtle). **DIET**. *Rhinoclemmys rubida* occurs along the west coast of México from Jalisco to Chiapas and in the lowlands of the Río Balsas Basin. Little is known about its feeding habits. Ernst and Barbour (1989. Turtles of the World. Smithsonian Institution Press, Washington, D.C. 313 pp.) state that "one was caught while eating a large caterpillar, but captives also eat plant foods." Here we report on feeding observations of wild and captive individuals of this species.

On 10 August 2001 at 1315 h., while conducting a herpetofaunal survey in the Cuixmala-Chamela Biosphere Reserve on the coast of Jalisco, México, one individual of *R. rubida* (130 mm CL) was observed feeding on a ripe fruit of *Carica mexicana* that was lying on the forest floor. Two other individuals (96, 112 mm CL) were within 2 m of the fruit, presumably attracted to it.

In captivity, three individuals of this species (149, 106, 119 mm CL) have accepted a variety of fruits, showing preference for *Carica papaya*. They have also eaten lettuce leaves, snails and earthworms.

We thank Susana García-Tellez, Elizabeth Raya-Lemus, and Miriam Quintero-Mora for assistance in field work and the Coordinación de Investigación Científica, UMSNH project 5.5 for financial assistance.

TRACHEMYS DECUSSATA ANGUSTA (North Antillean Slider). **LONGEVITY.** Documented records of natural (non-captive) longevity in aquatic turtles are relatively scarce. Extensive research on the Yellow-bellied Slider, *Trachemys scripta scripta*, in South Carolina (Gibbons 1990. Life History and Ecology of the Slider Turtle. Smithsonian Inst. Press, Washington, D.C. 368 pp.) has provided the best estimates. Gibbons and Semlitsch (1982. J. Anim. Ecol. 51:523–527) reported that this temperate climate species has a maximum lifespan of 35 years. However, little is known about longevity of slider turtles (*Trachemys*) in the tropics. Moll and Legler (1971. Bull. Los Angeles Co. Mus. Nat. Hist.11:1–102) studied a population of *T. venusta* in Panama and identified a large female (323 mm carapace length, CL) which was only 13–14 years old. They speculated that 30 years is a logical estimate of longevity for that population, but were unable to provide any direct evidence.

As an adjunct to a larger population study of slider turtles (*T. decussata angusta*) on Grand Cayman B.W.I. (Seidel 1990. J. Herpetol. 24:191–196), a small freshwater pond was sampled for turtles in 1983. The pond, locally known as "mud hole" at Newlands, is 8.5 km E. of George Town, Grand Cayman. The island has a tropical climate with daily mid-temperatures which peak at 28.4°C in July and fall to a minimum of 24.8°C in February (Burton 1994. *In* Brunt and Davies [eds.], The Cayman Islands, Natural History and Biogeography, pp. 51–60. Kluwer Acad. Publ., Netherlands). From 1 April–2 May 1983, 28 adult *T. decussata* were captured in baited hoop-nets; then measured, sexed, marked, photographed, and released. Each turtle was numerically coded by notching the marginal scutes (and underlying peripheral bones) according to a system modified from Cagle (1939. Copeia 1939:170–173). Their size ranged from 149–271 mm CL (plastron length, PL, 129–230 mm).

During a return visit to Grand Cayman 15 years later (1998), three baited hoop-nets were set at "mud hole" on 28 March. Among five adult sliders captured, one female and one male were recaptures marked in 1983. The notches on these two turtles were very worn, but discernable, and positive identification was also verified by comparison to photographs. When initially captured in 1983, the female was a young adult (165 mm PL, 189 mm CL) and at least 5–6 years old (Seidel, *op. cit.*). Upon recapture in 1998 she demonstrated considerable growth over 15 years (reaching 214 mm PL, 251 mm CL) and was ca. 21 years old. Eggs were not detectable by palpation. The recaptured male was older than the female when they were initially marked in 1983. At that time he was 159 mm PL and 189 mm CL, showed evidence of melanism

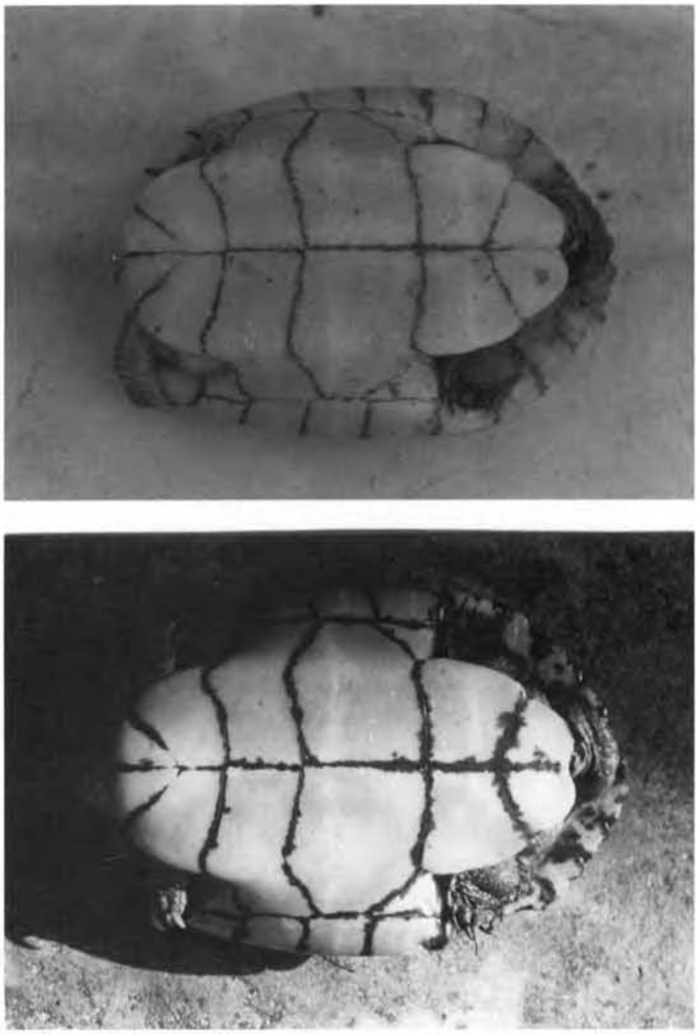

FIG. 1. Ventral views of a male *T. decussata* on Grand Cayman captured in 1983 (above) and recaptured in 1998 (below). The narrow dark areas evident along plastral seams in both photographs are typical of the melanistic pattern for this species (Seidel 1988. Amer. Mus. Novitates 2918:1–41).

(Fig. 1), and was probably more than 12 years old (Seidel, *op. cit.*). Although variable, male *T. scripta* in South Carolina generally exhibit signs of melanism after 10–14 years (Gibbons, *op. cit.*), similar to the approximate age melanism develops in *T. decussata* on Grand Cayman (Seidel, *op. cit.*). Upon recapture in 1998, the male was 169 mm PL, 204 mm CL, and at least 27–30 years old. Maximum longevity for sliders on Grand Cayman is probably >30 because Seidel (*op. cit.*) reported that males reach plastron lengths of 191–210 mm, and females 251–270 mm PL.

The natural history of slider turtles in the tropics shows a number of parallels to temperate populations, including similar reproductive strategies (Moll and Legler *op. cit.*). Nevertheless, an eminent difference in temperate climates is that turtles remain dormant (torpid) and demonstrate arrested growth for three to six months each year due to low environmental temperatures. There has been speculation that these turtles may remain physiologically "younger" compared to tropical turtles (which are active and growing over a longer portion of the year) and therefore reach greater chronological ages (Sacher 1978; cited in Gibbons 1987. BioScience 37:262–269). Data from the two *T. decussata* recaptured on Grand Cayman provides some evidence that tropical sliders may live as long in natural populations as their temperate relatives.

I thank Gina Ebanks-Petrie (Director of Environment, Cayman Islands government) and Fred Burton (Director of Environmental Programs, National Trust for the Cayman Islands) for their assistance and permission to conduct fieldwork. I thank Marshall University for partial financial support, Margarita Seidel for field assistance, Whit Gibbons for comments on the manuscript, and Mandy Stuck for typing.

LACERTILIA

CALLOPISTES PALLUMA (Chilean Racerunner, Iguana Chilena). **CANNIBALISM**. Intraspecific predation is well documented in lizards (Mitchell 1986. Cannibalism in Reptiles: A Worldwide Review. SSAR, Oxford, Ohio. 37 pp), but rarely reported among South American teiids. *Callopistes palluma* is a moderate-sized (81.5–173.0 mm SVL) teiid that inhabits extended sand burrows in scrubland habitats of northern Chile (Donoso-Barros 1966. Reptiles de Chile. Ediciones de la Universidad de Chile, Santiago, Chile. 458 pp.). Dietary data indicate that *C. palluma* feeds mostly on plants and invertebrates (Fuentes 1976. Ecology 57:3–17). In Fray Jorge National Park, a diet of small rodents (*Abrothrix olivaceus*), lizards (*Liolaemus*), and invertebrates has been reported (Mellado 1982. Acta Vertebrata 9:372–373). However, as intraspecific predation is unrecorded in *C. palluma*, we describe an instance here.

At 1725 h on 6 November 2002, during a study of *C. palluma* thermal ecology, we collected an adult male (123.3 mm SVL; 45.1 g; 20.1 mm head width) at Chacrita, Vallenar, Provincia de Atacama, Chile (28°23'39.3"S, 70°42'49.4"W; elev. 644 m). The habitat is a scrubland with the shrubs *Encelia canescens* (Asteraceae) and *Skytanthus acutus* (Apocynaceae) as dominants. While processing the lizard and recording temperature data, it regurgitated a juvenile female (86.2 mm SVL; 11.7 g; 13.4 mm head width) of the same species (Fig. 1). *Callopistes palluma* is sexually dimorphic in ventral color (females white, males red)

FIG. 1. Male of *Callopistes palluma* regurgitating a juvenile female of the same species.

(Donoso-Barros, *op. cit.*), so we were certain of the smaller lizard's gender. This observation represents the first record for cannibalism in this species.

This specimen was deposited in the herpetological collection of the Museum of Zoology at the University of Concepción (MZUC27485). We thank Viviane Jerez and Jaime Pizarro for field assistance.

Submitted by **MARCELA A. VIDAL** and **JUAN CARLOS ORTIZ**, Departamento de Zoología, Facultad de Ciencias Naturales y Oceanográficas, Universidad de Concepción, Casilla 160-C, Concepción, Chile; e-mail: (MAV) marvidal@udec.cl.

CNEMIDOPHORUS ALPINUS (Mexican Alpine Whiptail Lizard). **REPRODUCTION.** *Cnemidophorus alpinus*, the least understood gonochoristic species in the genus, is known only from small areas in the states of Puebla, Tlaxcala, and Veracruz in southern México (Maslin and Walker 1965. Univ. Colorado Stud., Series in Biol.19:1–8; Walker 1980. J. Herpetol. 14:353–359; Sanchez-Herrera and Lopex-Garcia 1987. Herpetol. Rev. 18:41). Here, I report on 3 additional specimens of this rare whiptail and include preliminary data on its reproductive characteristics.

I recently discovered 3 adults of *C. alpinus* in the Texas Cooperative Wildlife Collection (TCWC) provisionally identified as *C. septemvittatus* that were collected 13 May 1973 by J. R. Dixon and F. S. Hendricks in Tlaxcala, at the upper altitudinal limits known for the genus. Two specimens (TCWC 38308–09) were collected 2.9 km (1.8 mi) E of Huamantia at 2377 m (7800 ft); the remaining animal (TCWC 38312) was from 7.5 km (4.7 mi) E of Huamantia at 2468 m (8100 ft). The sexually mature male (84 mm SVL; TCWC 38312) has swollen testes 7.5–8.0 mm in length. One adult female (84 mm SVL; TCWC 38308) has 3 yolked eggs 8–10 mm in diameter in each ovary. The remaining individual (82 mm SVL; TCWC 38309) has 7 eggs (7.5–8.5 x 13–14 mm), 3 in the left oviduct and 4 in the right oviduct.

These data, the only available on clutch size in *C. alpinus*, reveal an unexpectedly high fecundity in this medium-sized highlands whiptail. In the giant species *C. sacki sacki* at 500–1600 m in Puebla and Oaxaca (Walker 1981. J. Herpetol. 15:321–328), females must be 105–120 mm to produce clutches of 6–7 oviductal eggs 10 x 16 mm in size that match the numbers of eggs in the two much smaller *C. alpinus* females from Tlaxcala reported here. In *C. gularis colossus* at 500–1550 m in Queretaro (Dixon et al. 1971. Herpetologica 27:244–354), the largest females (84 mm SVL) had clutches of 5 or fewer eggs.

I thank Kathryn Vaughan (TCWC Collection Manager) for permission to study specimens in her care.

CNEMIDOPHORUS COSTATUS BARRANCARUM (Barranca Whiptail Lizard). **HABITAT**. *Cnemidophorus costatus barrancarum* (corrected spelling of *barrancorum* on advice of HMS) is one of many named, but biologically unknown, reptiles in remote areas of México. Information on the habitat of this whiptail lizard is limited to a remark by Zweifel (1959. Bull. Amer. Mus. Nat. Hist. 117:57–111) that it occurs in Tropical Deciduous Forest. We describe habitat characteristics for *C. c. barrancarum* based on the observations and collections made by the first author on 13–17 July 2000 and 16–19 June 2001 at lowland sites at 435–687 m in the Barranca Region, Municipality of Batópilas, southwestern Chihuahua, México. Voucher specimens of the taxon obtained in the municipality are: El Duraznito, 27°0'32.4"N, 107°46'3.6"W [16 July 2000 (JLE 5918)]; N of Batópilas near km 50.5 on Chihuahua Hwy 75 from Samachique to Batópilas, 687 m, 27°6'53.8"N, 107°39'52.4"W [16 June 2001 (JLE 7316); 17 June 2001 (JLE 7317–7319)]; Río Batópilas near Batópilas [18 June 2001 (JLE 7373)]; Batópilas (town), Arroyo El Camuchil, 435 m, 27°1'34.1"N, 107°45'44.5"W [17 July 2000 (JLE 5940); 19 June 2001 (JLE 7369)]; Satevo, 567 m, 26°59'25.8"N, 107°45'52.9"W [18 June 2001 (JLE 7328–7330)]; Satevo Church, 26°59'19.4"N, 107°42'52.7"W [15 July 2000 (JLE 5910)]; along road to Satevo [15 July 2000 (JLE 5908, 5909)]. *Cnemidophorus costatus barrancarum* is the only known whiptail lizard inhabitant of the tropical lowland intrusion into the Barranca Region of southwestern Chihuahua. This area consists of deep canyons with steep sides eroded out of the Sierra Madre Occidental by several river systems. In the vicinity of the old mining town Batópilas (pop. ca. 2000), situated in a side canyon on the Río Batópilas, the entire canyon floor is arid with vegetation that corresponds to the Tropical Deciduous Forest of Rzedowski (1983. Vegetación de México. Limusa, México. 432 pp.) and the Short Tree Forest of Gentry (1942. Carnegie Institution of Washington. Publ. 527). Trees in this habitat are short to medium height (2–7 m), the most conspicuous species being *Pithecellobium dulce* (Guamúchil), *Gauzuma ulmifolia* (Guásima), *Ipomoea arborescens* (Palo Santo), and *Acacia* sp. (Acacia). There is little available land for cultivation in the region because of the steep canyon walls, human population density is low, and resulting environmental damage to the area is moderate in the context of México. Not unlike most species of whiptail lizards, *C. c. barrancarum* prefers disturbed habitats with open patches of substrate for basking, foraging, and escape sprints. It is easily the most ubiquitous and abundant ground-dwelling saurian species on the playas and roadsides near the Río Batópilas, as well as in many pig, donkey, and cattle corrals (averaging about 1 ha) in the area. This lizard was also observed in abundance along the road from Batópilas to La Bufa (air distance 17.3 km). The most conspicuous saurians observed with *C. c. barrancarum* were *Sceloporus clarkii*, *S. nelsoni*, *Urosaurus bicarinatus*, and *Ctenosaura macrolopha*. The small total sample size (N = 14) for *C. c. barrancarum* resulting from several days of collecting by JLE in 2000 and 2001 in the Barranca Region was not by choice. Despite its abundance, it was possible to collect only an occasional individual of this wary lizard with rubber bands, the use of handguns being prohibited in México.

CNEMIDOPHORUS COSTATUS BARRANCARUM (Barranca Whiptail Lizard). **REPRODUCTION**. Information on the reproductive biology of *Cnemidophorus costatus barrancarum* is limited to these comments published by Zweifel (1959. Bull. Amer. Mus. Nat. Hist. 117:57–111): clutch size, three oviductal eggs in each of two females of 71 mm SVL collected at Guirocoba, Sonora, México, on 10 and 11 August 1950; maximum size of females, 87 mm SVL; and maximum size of males, 107 mm SVL. We dissected 14 specimens of this teiid lizard collected by one of us on 15–17 July 2000 (JLE 5908–5910, 5918, 5940) and 16–19 June 2001 (JLE 7316–7319, 7328—330, 7369, 7373) at lowland sites at 435–687 m in the Barranca Region in the Municipality of Batópilas in southwestern Chihuahua, México. Complete locality data for this small sample of *C. c. barrancarum*, an abundant and wary lizard that is difficult to collect using a rubber band, are included in Lemos-Espinal et al. (2003. Herpetol. Rev. 34:365–366). The three males in the sample (JLE 5910, 7319, 7373 of 70, 81, 91 mm SVL) contained enlarged testes of 6.5–7.0 mm in length indicating sexual readiness when the lizards were collected. Nine females contained the following numbers of vitellogenic ovarian follicles (size range within the sample 3.5–9.0 mm): 67 mm SVL (potential for a clutch of 2 eggs); 71 mm (4); 75 mm (3); 78 mm (4); 78 mm (4); 83 mm (4); 83 mm (5); 86 mm (5); and 95 mm (7). Two females contained the following numbers of oviductal eggs (size range 9 x 14–8.5 x 14.5 mm): 73 mm SVL (3 eggs) and 77 mm (4). Data for our specimens combined with the report of Zweifel (*op. cit.*) established these reproductive characteristics for *C. c. barrancarum*; clutch size, 3.92 (2–7, N = 13) eggs; size of oviductal eggs, approximately 9 x 14 mm; size of reproductive females, 77.5 (67–95 mm) SVL; size range of mature males, 70–107 mm SVL; reproductive season, minimally June–August and probably much longer; and reproductive potential, likely multiple clutches given the maturation of both sexes at a small body size (67–70 mm SVL) within tropical regions of southwestern Chihuahua and southeastern Sonora. No individuals of *C. c. barrancarum* were observed by JLE during a visit to southwestern Chihuahua in the first half of April 2001, though *Sceloporus* lizards were active, suggesting that this teiid lizard may not be active throughout the year.

CNEMIDOPHORUS COSTATUS BARRANCARUM (Barranca Whiptail Lizard). **COLOR PATTERN**. Information on the color pattern of females of *Cnemidophorus costatus barrancarum* is limited to these remarks by Zweifel (1959. Bull. Amer. Mus. Nat. Hist. 117:57–111): "...all have the primary six stripes distinct. In none is the spotting well defined, and one as large as 78 mm, has only faint traces of light areas in the dark fields." We present a more complete description of the color pattern in females of this teiid lizard based on three males and 11 females collected by one of us on 15–17 July 2000 (JLE 5908–5910, 5918, 5940) and 16-19 June 2001 (JLE 7316–7319, 7328–7330, 7369, 7373) at lowlands sites (elev. 435–687 m) in the Barranca Region in the Municipality of Batópilas in southwestern Chihuahua, México. Complete locality data for this sample are included in Lemos-Espinal et al. (2003. Herpetol. Rev. 34:365–366). Data for the number of granules (scales) between the paravertebral stripes (PV) and percentage of the number of granules around midbody located between the paravertebral stripes (PV/GAB x 100) in 11 gravid females of *C. c. barrancarum* are: PV, 13.4 (12–15) and PV/GAB, 13.8 (11.8–16.8). All females have a pair of incomplete ventrolateral stripes, one on each side of the body from beneath the ear to the postaxillary region, and six complete primary stripes configured in three bilateral pairs which subdivide the dorsal ground color on each side of the body into lower lateral, upper lateral, and dorsolateral dark fields. On each side of the body there is a wide lateral stripe from below the eye onto the anterior surface of the thigh, an intermediate width dorsolateral stripe from the superciliary scales onto the tail, and a narrow paravertebral stripe from the lateral parietal scale to the base of the tail. The vertebral (middorsal) field between the paravertebral stripes is either occupied by a brown band or two thinly divided secondary stripes. In JLE 7369 (67 mm SVL), which is very similar to the smallest mature male in the sample (JLE 5910, 70 mm SVL), the vivid stripes are hues of off-white to dull cream, the fields are black-brown (except for gray-tan near the ventral scales), and faint incipient spots are apparent in the posterior parts of the dorsolateral fields. Only one female (JLE 5940; 83 mm SVL) differs markedly from having the sharply contrasting pattern of stripes and fields apparent in JLE 7369. In JLE 5940, contrast between the fields and stripes is much reduced, incipient spots are present in all fields except the middorsal, and there is evidence of spot formation on the primary stripes. The largest individual of *C. c. barrancarum* (JLE 7330, 95 mm SVL) verified that females of this form undergo marked ontogenetic changes in color pattern from the striped dorsum in juveniles and young adults to development of spots on the stripes, hind legs, base of the tail, and in the upper lateral and dorsolateral fields. Apparently, complete loss of the stripes does not occur in females of *C. c. barrancarum.* Tail colors among the females in the sample are: basal third, brown to dark tan and distal part, buff-tan. Ventrally, these females vary from cream to dull blue-green with no evidence of the black pigment that is present in large males of the subspecies.

Incomplete knowledge of color pattern in females of *C. c. barrancarum* contributed to Zweifel's (*op. cit.*) uncertainties about its separation from parthenogenetic *C. exsanguis* and gonochoristic *C. gularis scalaris* in Chihuahua. Both of these species are now known to be allopatric to *C. c. barrancarum* and, because of their greater profusion of vivid dorsal spots and much lower PV and

PV/GAB numbers (Walker, unpubl. data; Walker et al. 2001. Copeia 2001:747–765), should not be confused with the Barranca Whiptail.

CYCLURA PINGUIS (Stout Iguana, Anegada Rock Iguana). **JUVENILE BEHAVIOR**. Following its repatriation in 1986, *Cyclura pinguis* is flourishing on Guana Island, British Virgin Islands (Lazell 2002. Ecol. Restor. 20:179–185). Recently hatched juvenile iguanas are now frequently encountered in early October, but their behavior remains unstudied. As part of a census effort, the marking of iguanas during October 2002 afforded the opportunity to follow animals and individually identify them. Here, we provide preliminary observations on agonistic behaviors of juvenile *C. pinguis* from Guana Island.

During the month-long study, a white water-based latex paint was used to individually mark iguanas throughout the 340-ha island. Sightings occurred throughout Guana Island (18°38'N, 65°25'W), though most were near the hotel area (for additional information on Guana see Lazell 1996. Guana Island. The Conservation Agency, Jamestown, Rhode Island, 20 pp.). We observed no obvious adverse effects from the marking. Recently hatched individuals were repeatedly sighted, typically within a 10-m radius of previous sightings. Overall, we observed 13 marked and an unknown number of unmarked juvenile *C. pinguis* during the month. Many of them were observed on multiple occasions, resulting in over 35 sightings. All observations were made between 0800 and 1700 h.

On four separate occasions, a juvenile *C. pinguis* was seen displaying aggressive behaviors towards two other juveniles seen in the same area. Agonistic behaviors were varied. Head bobs and push-ups were seen in all interactions and were the most common aggressive behaviors observed. In one case, biting occurred during the display stage. During one lengthier interaction that lasted > 10 min, we also observed full apposition (the lizards were parallel to one another with their heads pointing in the same direction) and lateral compression of the bodies such that the side facing the other lizard appeared larger than normal. Chasing typically followed up to 10 min of displays, lasted less than 1 min, and covered less than 5 m. The loser left the area following each interaction, though the distance it traveled is not known. In the case of one pair of lizards, the lizard subsequently returned and interactions were observed daily for three days. In the other case, we never saw the loser again following the interaction.

Cyclura pinguis adults are known to avoid the centers of activity of conspecifics (Mitchell 1999. *In* Alberts [ed.], West Indian Iguanas: Status Survey and Conservation Action Plan, pp. 45–70. IUCN/SSC West Indian Iguana Specialist Group. IUCN, Gland, Switzerland and Cambridge, UK) and display aggression towards both adults and juveniles that approach them (N. Mitchell, unpubl. observ.). Our observations imply that juvenile *C. pinguis* begin establishing territories early in life, and that aggressive encounters may be important in determining the boundaries of these nascent territories.

We thank the staff of Guana Island for technical assistance, and Henry and Gloria Jarecki for access to Guana Island. Through a grant from the Falconwood Foundation, The Conservation Agency provided financial support. This is manuscript T-9-968 of the College of Agricultural Sciences and Natural Resources, Texas Tech University.

CYCLURA PINGUIS (Stout Iguana, Anegada Rock Iguana). **JUVENILE PREDATION**. *Cyclura pinguis* was repatriated to Guana Island, British Virgin Islands, in 1986. Its population has since expanded considerably (Lazell 2002. Ecol. Restor. 20:179–185), and sightings, especially of hatchlings, have become increasingly common. Nevertheless, the ecology of this critically endangered species remains poorly understood. Since 2000, our regular observations of recently hatched iguanas in early October have afforded the opportunity to better understand their ecology. In particular, predation on *C. pinguis* by other than exotic predators (feral cats; Mitchell 2000. *In* Reading and Miller [eds.], Endangered Animals: A Reference Guide to Conflicting Issues, pp. 22–27. Greenwood Press, Westport, Connecticut) has not been recorded. Here, we describe three predation events on juvenile *C. pinguis* involving the native fauna of Guana Island (18°38'N, 65°25'W).

Two observations involved the locally abundant Puerto Rican racer, *Alsophis portoricensis*. On 12 October 2001 at 1530 h, we were told by Guana Hotel staff that an adult snake had been seen attempting to swallow a juvenile iguana and had the head of the lizard in its mouth. When we arrived, the snake was gone, and the juvenile iguana (106 mm SVL), already dead, had been left by the snake. The sighting occurred on a road, in an area containing both ornamental and native scrub flora. The dead iguana was preserved, tagged, and catalogued (JL F-4890), but remains in the British Virgin Islands because of CITES regulations.

We made the second observation on 9 October 2002, in an area characterized by ornamental vegetation in the Guana Hotel area. At ca. 1840 h, the snake was coiled around the midsection of the lizard and biting the lizard's chest. The lizard (ca. 100 mm SVL) was still struggling weakly, but appeared to have already been envenomated. We took photographs and video footage of the ingestion process, which was completed at ca. 2040 h. The snake, subsequently caught, measured 68 cm SVL (tail length = 35 cm). *Alsophis portoricensis* primarily preys on lizards (Henderson and Sajdak 1996. *In* Powell and Henderson [eds.], Contributions to

West Indian Herpetology: A Tribute to Albert Schwartz, pp. 327–338. SSAR, Ithaca, New York); these are the first records of iguanas in its diet.

We observed a third predation event on 8 October 2002 around 1530 h. A female kestrel (*Falco sparverius*), locally abundant on Guana (Lazell 1996. Guana Island. The Conservation Agency, Jamestown, Rhode Island, USA. 20 pp.), was observed feeding on a freshly killed juvenile iguana (ca. 110 mm SVL), which it had carried up to a tree perch. We recorded the feeding process, which began at the head of the lizard, for ca. 15 minutes with photographs and videotape. At the end of this period, the bird flew off with the partially consumed lizard in its talons. Much of the head was gone by this time, but the body and tail of the lizard remained mostly untouched.

We thank Christine Matthias, Susan Slater, and Roy Snelling for helping us locate these events, the staff of Guana Island for technical assistance, and Henry and Gloria Jarecki for access to Guana Island. The Conservation Agency through a grant from the Falconwood Foundation provided financial support. This is manuscript T-9-969 of the College of Agricultural Sciences and Natural Resources, Texas Tech University.

ELGARIA MULTICARINATA (Southern Alligator Lizard) **BEHAVIOR**. Mating behavior in alligator lizards has been described or illustrated for *Elgaria coerulea* (Svihla 1942. Copeia 1942:54; Vestal 1940. Copeia 1940:51; Vitt 1973. Herpetologica 29:176–184), *E. kingi* (Bowker 1986. Herpetol. Rev. 17:20), and *E. multicarinata* (Fitch 1935. Trans. Acad. Sci. St. Louis 29:1–38; Stebbins 1959. Reptiles and Amphibians of the San Francisco Bay Region, University of California Press, Berkeley, California. 72 pp.), but available data address only interactions between one male and one female. Herein, we report an observation involving two males and one female *Elgaria multicarinata*.

On 12 April 2002 at 1614 h, one of us (DJR) observed 3 adult *E. multicarinata* (1 female, 2 males) that were actively engaged in a succulent garden in La Cañada-Flintridge, Los Angeles County, California, USA (34°14'05"N, 118°13'29"W). Sex was determined by comparing observed behavior and morphology with that illustrated in the literature (e.g., Bowker 1986, *op. cit.*; Fitch 1935, *op. cit.*; Vestal 1940, *op. cit.*). One male (A, middle, Fig. 1) was gripping the female by the head while the other male (B, bottom, Fig. 1) was attached in the same way to male A. Male A had oriented his body alongside the female and was rotating his tail over the female in an attempt to position his cloaca for copulation. Male B was exhibiting similar body posturing, and because of their positioning, posturing appeared directed towards male A (Fig. 1) instead of the female. After ca. 10 minutes in this position, the lizards became aware of the observer, disengaged from each other, and moved off into nearby vegetation, negating further observations.

The head-gripping posture of male A on the female agrees with

FIG 1. Three interacting *Elgaria multicarinata* (Top: female; Middle: male A; Bottom: male B).

descriptions of copulation or attempted copulation for *E. multicarinata* (e.g., Fitch 1935, *op. cit.*; Stebbins 1959, *op. cit.*). The positioning of the lizards implied that male A had initiated contact with the female when male B arrived. It is unclear whether the behavior of male B was copulatory, agonistic toward male A, or both.

Submitted by **KENT R. BEAMAN**, Section of Herpetology, Natural History Museum of Los Angeles, 900 Exposition Blvd., Los Angeles, California 90007, USA (e-mail: heloderma@adelphia.net) and **DONALD J. REINING**, 5535 Rock Castle Drive, La Cañada-Flintridge, California 91011, USA.

HEMIDACTYLUS MABOUIA (Tropical House Gecko). **MORTALITY**. Predation episodes involving potentially lethal prey provide insights into the risks to which predators may be exposed. Here, we report a lethal predatory episode involving the house gecko, *Hemidactylus mabouia*.

On 2 July 2002 at 0930 h, one of us (DGL) saw a female house-gecko (59 mm SVL) attack a male spider (11.5 mm body length) of the genus *Ctenus* (Ctenidae; identification to species was not possible as both palps were missing) on a rough-textured wall in the Museum of Zoology Profesor Mello Leitão in Santa Teresa (19°56'S, 40°36'W), state of Espirito Santo, Brazil. Seconds after capturing the spider and attempting to swallow it, the gecko began to fall, but kept hanging on the wall by its midbody with all four legs limp and spread apart. The gecko, which remained motionless except for a few spasms, was picked up and placed on a table, where it made no attempt to move. After ca. 30 min, the gecko ceased to show signs of life (i.e., no breathing and heartbeat). The spider, apparently injured (examination revealed a dent in its cephalothorax and some broken legs), remained inside its mouth until we removed it.

The spider probably bit the gecko inside its mouth in self defense, and we assume that its venom killed the lizard. Symptoms exhibited by the gecko following the attack on the spider strongly suggest

the action of a neurotoxic venom (R. Baptista, pers. comm.). Some ctenid spiders, particularly members of the genus *Phoneutria*, are known to have potent venom with neurotoxic effects and can be deadly even to humans (e.g., Bücherl 1969. Am. Zool. 9:157–159; Schenberg and Pereira Lima 1978. *In* Bettini [ed.], Arthropod Venoms, pp. 217–245. Springer-Verlag, New York). Members of the genus *Ctenus*, which are generally much smaller, apparently lack venoms potent enough to harm large vertebrates, but may present a significant risk to arthropods and small vertebrates (Massary and Ineich 1997. Rev. Fr. Aquariol. 24:3–4; Massary 1999. Herpetol. Rev. 30:167). This episode indicates that house geckos can be at risk during predation attempts on ctenid spiders.

The gecko along with the spider (MNRJ 9802) were deposited at the Museu Nacional, Rio de Janeiro. We thank Renner Baptista for identifying the spider, critically reading this note, and giving helpful suggestions.

MABUYA UNIMARGINATA (Central American Mabuya). **ENDOPARASITES.** *Mabuya unimarginata* (= *M. mabouya*), *sensu* Wilson and McCranie (2002. Herpetol. Rev. 33:90–94) occurs from sea level to ca. 1100 m in a variety of forest habitats in Honduras, Central America (Meyer and Wilson 1973. Contr. Sci. Nat. Hist. Mus. Los Angeles County 244:1–39). To our knowledge, this is the first report of helminths from *Mabuya unimarginata*.

Our report addresses 8 *M. unimarginata* (mean SVL = 70.4 mm ± 3.2 SD, range = 66–76 mm) from the Los Angeles County Natural History Museum (LACM 47741–47745, 47747, 47748, 47750). Lizards were collected 29 July 1967 at Coyoles (14°58'N, 86°41'W), Department of Yoro, Honduras, fixed in 10% formalin then preserved in 70% ethanol. The abdominal cavity of each lizard was opened, the gastrointestinal tract removed, slit longitudinally, and examined under a dissecting microscope. Helminths were removed to a drop of undiluted glycerol for identification.

One species of Nematoda, *Physalopteroides venancioi* (Physalopteridae) was found lying free in the stomach or large intestine. Specimens were placed in a vial of 70% ethanol and deposited in the United States Parasite Collection (USNPC), Beltsville, Maryland as USNPC 92624. Prevalence of infection (number infected/sample examined x 100) was 4/8 (50%), mean intensity ± 1 SD (number of nematodes/number of infected lizards) was 4.8, range was 1–10.

Hosts of *P. venancioi* include *Bufo paracnemis* of Paraguay (Lent et al. 1946. Mem. Inst. Oswaldo Cruz 44:195–214), *Ameiva ameiva* of Brazil (Vrcibradic et al. 2000a. J. Parasitol. 86:1163–1165), and *Mabuya agilis*, *M. macrorhyncha*, and *Tropidurus torquatus* also of Brazil (Vrcibradic et al. 2000b. Amphibia-Reptilia 21:307–316). *Physalopteroides venancioi* has been found in the stomach, small and large intestines of its hosts (Vrcibradic et al. 2000b, *op. cit.*), but most likely, like other physalopterids (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission 2nd Edition. CABI Publishing, Oxon, UK. 650 pp.), it is a stomach parasite and those found in the intestines are dead or dying, soon to be passed in the feces. *Mabuya unimarginata* represents a new host record for *P. venancioi*; Honduras is a new locality record. This is the first report of *P. venancioi* from Central America.

We thank D. Kizirian (Natural History Museum of Los Angeles County, Los Angeles, California) for permission to examine *M. unimarginata*.

NOROPS HETEROPHOLIDOTUS (NCN). **DEWLAP COLORATION**. Dewlap color in anoles plays a pivotal role in species recognition and intraspecific interactions (e.g., Macedonia and Stamps 1994. Ethology 98:246–264), and as a consequence, biologists often use it to identify species. *Norops heteropholidotus*, an anole in the *crassulus* species group known from isolated highlands in El Salvador and Honduras (Köhler and McCranie 2002. Herpetofauna 20:12–13), has had its dewlap color described as "erdbeerrot" (strawberry red) (Mertens 1952. Abh. Senckenberg Naturforsch. Ges. 487:1–120) and "rot mit hell-bis dunkelbraunen schuppen" (red with light to dark brown scales) (Köhler 2000. Reptilien und Amphibien Mittelamerikas. Band 2: Krokodile, Schildkröte, Echsen. Herpeton Verlag, Offenbach, Germany. 158 pp). However, these descriptions were solely based on preserved specimens, and *N. heteropholidotus* has remained poorly known. Here, we provide the first reports on *N. heteropholidotus* dewlap coloration in life, female dewlap coloration, and the striking change in gorgetal scale color in the male dewlap.

In December 2001, during fieldwork on Cerro las Nubes, Departamento Chalatenango, El Salvador (14°23'33"N, 89°6'17"W; elev. 2090 m) we observed > 25 *N. heteropholidotus* and collected 9 (YPM 12422–23, 12379–85). Adult females consistently displayed a small orange-yellow dewlap, the rear margin of which extended posteriorly to the point of forelimb insertion. Males had a large strawberry red dewlap in life (maroon in preservative), the rear margin of which extended a distance posteriorly to the axilla roughly the diameter of the forelimb. The large gorgetal scales of the male dewlap displayed a striking color change depending on time of collection. In most specimens these scales were white, sometimes with a light speckling of gray pigment. However, males observed roughly before 1000 h had uniformly dark gray gorgetals. Five out of seven lizards caught before about 1000 h would have dark, slate gray gorgetals that would change to almost perfectly white in 3–4 min, while lizards were being held or kept in collecting bags. Male *N. heteropholidotus* caught after 1000 h generally displayed white gorgetals, although some traces of darker pigmentation might be present. When preserved in 70% ethanol, with or without previous fixation in 10% formalin, gorgetal scales

on the male dewlap are white, occasionally with a pink or tan hue, and their melanophore density varies.

Anoles of the genus *Norops* are capable of considerable color change, but gorgetal scale coloration is generally not variable (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago. 934 pp.). Darkening of the gorgetal scales in *N. heteropholidotus* may play a thermoregulatory role since these anoles inhabit high elevation (> 1800 m) cloud forest zones. During the period of field work at Cerro las Nubes, the minimum temperature would drop to 7°C at night, and the lizards would become active when the daytime temperature exceeded ~18°C. Other Central American highland lizards are known to display metachrosis, possibly as a way to help absorb solar radiation (Robinson 1983. *In* Janzen [ed.], Costa Rican Natural History, pp. 421–422. University of Chicago Press, Chicago, Illinois).

Specimens of *N. heteropholidotus* were collected under permits from the Ministerio de Medio Ambiente y Recursos Naturales, San Salvador, El Salvador (MARN-DGPN-AIMA-8-01 and MARN-DGPN-AIMA-01-2002) and are deposited in the herpetology collection of the Yale Peabody Museum of Natural History.

PANTODACTYLUS SCHREIBERSI (NCN). **HABITAT AND DIET**. *Pantodactylus schreibersi* is a small (to 2 cm total length), common gymnophthalmid lizard widespread in southeastern South America. It inhabits a wide range of habitats from montane scrublands and rocky hillsides to grasslands of the pampas, trashpiles, and gardens (Achaval and Olmos 1997. Anfibios y Reptiles del Uruguary. Facultad de Ciencias, Montevideo, Uruguay. 128 pp.; Cei 1993. Reptiles del Noroeste, Nordeste y Este de la Argentina. Mus. Reg. Scien. Natur. Torino, Monogr. XIV, Turin, Italy. 949 pp.). Despite this broad pattern of habitat use, association with water, as occurs in some microteids (e.g., *Neusticurus*: Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.), is unknown. Hence, we provide a preliminary report of *P. schreibersi* use of semi-aquatic habitat.

Our observations took place near midday on 21 July 2001, while using a 3.5 m x 1.2 m drag seine as a bag to lift floating mats of camalotes (water hyacinths, *Eichhornia crassipes*) out of the Paraguay River near Fuerte Olimpo, Departamento Alto Paraguay, Paraguay (21°02'30"S, 57°53'10"W; elev. 75 m). During this effort, we were surprised to capture two female *P. schreibersi*, one from each of two different floating mats. When each individual was briefly placed in water to observe their behavior, both swam with ease using a snake-like undulating motion, which suggests that they were not in this semi-aquatic habitat simply by accident.

Stomach contents of these animals reinforced the notion of semi-aquatic habitat use. The stomach of one specimen (32.5 mm SVL) contained an orthopteran nymph (Gryllidae), a homopteran (Fulgoridae), a moth (Lepidoptera), and a nematode parasite. The other lizard (41.9 mm SVL) contained 4 spiders (Araneae), an empty spider egg case, and plant material. Similar prey were common in our camalote seine-hauls. Fifty-six percent of prey in 8 *P. schreiberi* from Brazil were similar (Milstead 1961. Copeia 1961:493–495), including a corresponding preponderance of arachnids.

Specimens (MNHNP 10008–09) and stomach contents are deposited in the Museo Nacional de Historia Natural del Paraguay. We thank Ignacio Avila for help collecting, Bolivar Garcete for identification of the stomach contents, and Norman Scott for his advice.

UMA EXSUL (Fringe-toed Sand Lizard). **PREDATION**. *Uma exsul* is endemic to the sand dune systems in Viesca, 70 km SE Torreón (State of Coahuila), Mexico. Its biology and status have been moderately well studied (Gadsden et al. 2002. Bol. Soc. Herpetol. Mex. 9:51–66), and *Gambelia wislizenii* is the only lizard species in this dune system that was considered a predator. Here, we add the teid *Cnemidiphorus tigris marmoratus* to the list of predators on *U. exsul*.

At 1530 h on 24 July 2002, during a survey of the sand dune system, we encountered an adult (180 mm SVL) male *C. t. marmoratus* chasing a young-of-the-year (32 mm SVL) *U. exsul*. We observed the *C. t. marmoratus* pursuing the *Uma* up a dune 1.8 m high in a chase that lasted < 30 seconds. The young *Uma* was caught by the neck, ingested head first, and swallowed with undulatory movements of the body; the entire process lasted about 3 minutes.

At 1200 h on 25 July 2002, we saw another adult *C. t. marmoratus* chasing a young-of-the-year *U. exsul*, but this time the *Uma* managed to scape. Predation on hatchling lizards, including their own young, has been reported for some *Cnemidophorus* (Berrian and Banta 1979. Bull. Maryland Herpetol. Soc. 15:61; Etheridge and Wit 1982. Herpetol. Rev. 13:19; Galina et al. 1998. Herpetol. Rev. 29:237) and failed predation on larger individuals (Lichtenstein and Lichtenstein 1987. Herpetol. Rev. 18:73) may indicate that opportunities for predation are largely restricted to hatchlings.

We thank Ivonne Rivera for her help in the field.

CROCODYLIA

CROCODYLUS ACUTUS (American Crocodile). **CANNIBALISM.** Cannibalism is presumed to be common in crocodilians and may be an important population regulating mechanism in this group (e.g., Hutton 1989. Amer. Zool. 29:1033–1049; Polis and Myers 1985. J. Herpetol. 19:99–107). Cannibalism has been observed in a few species (e.g., *Alligator mississippiensis*: Delany 1986. J. Wild. Manage. 50:348–353; *Crocodylus niloticus*: Cott 1961. Trans. Zool. Soc. Lond. 29:211–357), but no published reports exist for the American crocodile (*Crocodylus acutus*). Here, we report cannibalism by juvenile *C. acutus*.

Our first observation was made 2 August 2000, while radio-tracking hatchling *C. acutus* at the Florida Power and Light Company's Turkey Point Power Plant in southeastern Dade Co., Florida, USA (25°26'14"N, 80°20'17"W). We tracked a transmitter signal to an unmarked juvenile crocodile of undetermined sex (80 cm total length [TL], 1.2 kg). Examination of this juvenile upon capture revealed that the transmitter was in its gut; we had originally attached it to a hatchling crocodile (26.6 cm TL, 60 g) on 20 July 2000. We then scanned the juvenile's abdomen for the identifying microchip (AVID Identification Systems, Inc., Norco, California) used to tag the transmitted hatchling and detected 8 microchips, each originally placed in a different *C. acutus* hatchling in 1999 or 2000, including that of the transmitted individual. This hatchling had been radio-tracked successfully for 5 days until on 1 August 2000 it made an unusually long move (262 m) from the previous day's location. This and a sudden reduction in transmitter signal strength motivated us to attempt to sight or capture the transmitted hatchling. Two of the other microchips detected in the juvenile crocodile's abdomen had been placed in hatchlings released at the same time and place as the radio-transmitted individual. The remaining 5 microchips were originally used to tag hatchlings in July 1999. We do not know the gut residence time of a microchip, so we cannot distinguish whether these hatchlings were recently (days to weeks) cannibalized by this juvenile, or whether these microchips had been retained as gastroliths for up to a year.

Our second observation involved a 117.5 cm TL (4.6 kg) *C. acutus* of undetermined sex captured in the cooling canal system of the Turkey Point power plant. This individual had been initially captured and marked by tail scute clipping on Key Largo and was later recaptured and microchipped in the cooling canal system of the Turkey Point power plant on 26 April 2000. On 19 April 2001, we recorded a microchip from its abdomen originally used to tag a 33.7 cm TL (100.8 g) *C. acutus* hatchling. That hatchling had been captured and released in the cooling canal system of the Turkey Point power plant on 12 August 2000.

The Florida Power and Light Company provided financial support, equipment, logistical support, and allowed us to work on their property. The University of Miami Department of Biology, the Army Corps of Engineers, the Department of Interior's Critical Ecosystem Studies Initiative, administered by the National Park Service, and the USGS's Florida Caribbean Science Center funded PMR as part of cooperative agreement number 1445-CA09-95-0111 with the University of Miami.

Submitted by **PAUL M. RICHARDS**, Department of Biology, Florida State University, Tallahassee, Florida 32306, USA (e-mail: prichards@bio.fsu.edu), and **JOSEPH WASILEWSKI**, Florida Power and Light Company, Turkey Point Land Utilization Homestead, Florida 33090, USA.

SERPENTES

BOTHROPS ATROX (Common Lancehead). **DIET**. In July 2001, a male *B. atrox* (LPHA 1789; 1040 mm total length) was collected by S. Claudino on the right bank of the Tapajós River, Itaituba (55°59'W, 4°17'S), Pará State, Brazil. The specimen was verified by Rubens Nobuo Yuki and was deposited in the scientific collection of the Linha de Pesquisa em Herpetologia da Amazônia in the Laboratório de Pesquisas Zoológicas (LPZ) of the Faculdades Integradas do Tapajós (FIT). The stomach contents were examined and found to contain a male *Mastigodryas boddaerti* (LPHA 1790; ca. 670 mm total length). The body of the *M. boddaerti* was contorted and apparently had been ingested head-first because its anterior region was oriented toward the intestine of the *B. atrox*, and was in an advanced stage of digestion. *Bothrops atrox* eat species of lizards (*Ameiva*, *Gonatodes*, *Tropidurus*, and *Cnemidophorus*) (Cunha and Nascimento 1982. Bol. Mus. Para. Emílio Goeldi, sér. Zool. 112:1–58), small birds, rodents (Cunha and Nascimento 1975. Bol. Mus. Para. Emílio Goeldi, nov. sér. Zool. 83:1–42), amphibians, and snakes ("*Leimadophis typhlus*" [= *Liophis typhlus*] and *Atractus torquatus*) (Egler et al. 1996. Herpetol Rev. 27:22–23; Greene 1997. Snakes: The Evolution of Mystery in Nature. Univ. California Press, Berkeley. 351 pp.).

Submitted by **JOSSEHAN GALÚCIO DA FROTA**, Linha de Pesquisa em Herpetologia da Amazônia (LPHA), Laboratório de Pesquisas Zoológicas (LPZ) das Faculdades Integradas do Tapajós (FIT), Rua Rosa Vermelha, 335, Santarém, Pará, Brazil, CEP: 68.010-200; e-mail: jgfrota@mailbr.com.br.

CHIRONIUS FLAVOLINEATUS (NCN). **PREDATION.** *Chironius flavolineatus* is a medium-sized colubrid snake with a wide distribution, from northern Brazil to northeastern Paraguay and central Bolivia, but little is known about its natural history (Dixon et al. 1993. Revision of the Neotropical Snake Genus *Chironius* Fitzinger [Serpentes, Colubridae]. Monografie XIII. Museo Regionale di Scienze Naturali. 279 pp.). It is a semiarboreal species (pers. obs.), and feeds mainly on frogs (Dixon et al., *op. cit.*). On 9 December 2001, during a diurnal road sampling of snakes at about 1030 h, we observed a white-tailed hawk, *Buteo albicaudatus*, perched on a tree branch ca. 2 m above ground, holding a snake. The observation was made on an unpaved road in a pristine shrubby grassland of Cerrado (savanna-like vegetation) at Itirapina Ecological Station (IES; 22°13'24"S, 47°54'03"W; ca. 750 m elev.), southeastern Brazil. Just after we spotted the hawk, it flew away with the snake in its talons. We followed the hawk by car and foot, whereupon the hawk released the snake and flew away. We found the dead snake on the ground. It was an adult female *Chironius flavolineatus* (estimated SVL 680 mm; SVL remaining 564 mm; tail length 375 mm; 155 remaining ventral scales) lacking the head and anterior portion of the body. The snake had several cuts and punctures along the body (N = 20) and a puncture on the tail, indicating that the hawk might have fought with the snake to subdue it. On the anterior portion of the body there were only cuts, and on the posterior portion there were

punctures and cuts, indicating that the hawk directed its strikes to the snake's head, probably to minimize the risk of injuries.

The voucher specimen of *C. flavolineatus* is deposited in the Museu de História Natural, Universidade Estadual de Campinas (ZUEC 2650). D. Zanchetta and the staff of Instituto Florestal allowed and facilitated our fieldwork at IES. FAPESP provided funds (00/12339-2) and grants to RJS (99/05664-5) and CAB (99/06245-6). We thank M. Martins and C. Nogueira for suggestions on the manuscript. This is publication number 9 of the project Ecology of the Cerrados of Itirapina.

CRISANTOPHIS NEVERMANNI (Black Road Guarder). **SIZE.** The record total length known for *Crisantophis nevermanni* is 82.8 cm (female, 66.0 cm SVL, 16.8 cm tail length) (Wellman 1963. Univ. Kansas Publ. Mus. Nat. Hist. 15:251–295; Villa 1971. J. Herpetol. 5:173–177). Here we report a female *C. nevermanni*, University of Costa Rica Museum of Zoology (UCR 16037), collected by MS on 13 October 2001, in Palo Verde National Park, in Cañas, Guanacaste (northwestern Pacific versant), Costa Rica, with total body length of 100.7 cm (85.2 cm SVL, 15.5 cm tail length, ca. 2 cm of tail missing). The specimen was found during the morning in the abandoned airstrip adjacent to the Palo Verde Lagoon. A large *Masticophis mentovarius* was also captured in the spot simultaneously. From the observed wounds on the *C. nevermanni*, it seems that the large snake was trying to prey on it.

Submitted by **ALEJANDRO SOLÓRZANO**, Serpentario Nacional, P.O. Box 2157-1002, San José, Costa Rica, and **MAHMOOD SASA**, Organization for Tropical Studies (O.T.S.), Costa Rica.

CROTALUS ADAMANTEUS (Eastern Diamondback Rattlesnake). **WINTER FEEDING.** The optimum temperature range for quickest, most complete digestion of prey items by snakes is usually between 27–29°C (Rubio 1998. Rattlesnake: Portrait of a Predator, Smithsonian Institution Press, Washington). Generally, digestion is completely inhibited and snakes regurgitate food at temperatures less than 10°C (Lillywhite 1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 422–477. Macmillan Publishing, New York). An oversized bolus and lower than preferred temperatures may result in putrefaction of prey.

In the Coastal Plain of southeastern Georgia, adults of two large snake species, the Eastern Indigo Snake (Colubridae: *Drymarchon corais couperi*) and the Eastern Diamondback Rattlesnake (Viperidae: *Crotalus adamanteus*), are frequently surface-active during the winter (December–February) when air temperatures exceed 12.7°C (Timmerman 1995. Bull. Florida Mus. Nat. Hist. 38, Pt. I[5]:127–158; D. Stevenson, unpubl. data). Both species use Gopher Tortoise (*Gopherus polyphemus*) burrows, nine-banded armadillo (*Dasypus novemcinctus*) burrows, stump holes, or similar retreats for winter dens. When found on the surface during the winter, individuals are typically close to their dens (Timmerman *op. cit.*; Moler 1992, *In* Moler [ed.], Rare and Endangered Biota of Florida, Volume III: Amphibians and Reptiles, pp. 181–186, Univ. Press of Florida, Gainesville). To what extent *C. adamanteus* or *D. c. couperi* feed during the winter is unknown. In this note, I discuss observations of winter feeding by adult *C. adamanteus* in Georgia.

An adult *C. adamanteus* collected 1 January 2002, 8.0 km SW of Glennville, Tattnall County, Georgia (31°55'N; 82°00'W) possessed a distinct bolus near midbody. The snake was found coiled on the surface in direct sunlight at 1230 h (air temperature of 9°C). The snake was held in captivity until 6 January at which time it was euthanized because of severe injuries it experienced while being captured. The snake, a post-parturient female (139.7 cm SVL, 148.6 cm TL, 3.12 kg with prey item) contained a partly digested, but essentially intact, adult eastern cottontail (*Sylvilagus floridanus*) in its stomach.

The snake probably ate the rabbit during unseasonably warm (19–27°C) weather 13–29 December 2001. During the first week of January 2002, southeastern Georgia experienced local snow flurries and ice on 2 January, and a low temperature of –7.2°C was recorded on 5 January. Although warm, sunny conditions with daytime highs ca. 22°C are common in winter in southern Georgia, extended blocks of cold weather or sudden cold snaps associated with passing fronts likely force all snakes underground and may compromise their ability to digest prey. Average high and average low winter (December–February) temperatures for the Glennville, Georgia area are 16.6°C and 4.4°C, respectively (NOAA 2001. Climatological Data Annual Summary, National Oceanic and Atmospheric Administration, Asheville, North Carolina).

Similar to the above observation, I found an adult *C. adamanteus* with a large bolus on the surface near a Gopher Tortoise burrow on 23 December 1992 in nearby Bryan County, Georgia. This snake was subsequently observed coiled on the surface near the burrow, probably basking to facilitate digestion, on warm days in early January 1993. However, during cold weather with daytime temperatures about 8°C (in early January) the snake evidently moved underground, as it was observed 1.5 m deep within the burrow or not found at all under these conditions.

Winter feeding has been reported for *C. adamanteus*, but not at a latitude this far north. Timmerman (*op. cit.*) reported that a male *C. adamanteus* (SVL = 135 cm) found dead 13 January 1998 (probably killed by a white-tailed deer) in northern Florida contained the remains of a mouse in its small intestine. Adult *C. adamanteus* with stomach boli have been found throughout the winter in central Florida (Martin 2003. *In* Timmerman and Martin, The Eastern Diamondback Rattlesnake Conservation Guide. SSAR Herpetol. Circ.), and adult snakes with boli have been found on two occasions during the winter in the Lower Coastal Plain of South Carolina (Jeff Humphries, pers. comm.).

C. adamanteus that take prey during the coldest months of the year may be individuals with low fat reserves—such as post-parturient females, males whose energy demands are stressed by mate-searching followed by unsuccessful foraging, or fast-growing juveniles (Timmerman and Martin, *op. cit.*). Snakes with boli observed on the surface may be attempting to maintain or attain

optimum temperatures for digestion, and basking could potentially expose the snakes to increased risk of predation (Lillywhite, *op. cit.*). An adult *C. adamanteus* (ca. 122 cm TL) I observed coiled on the surface 2 m from an armadillo burrow on a cool morning (12ºC, 22 December 1997; Liberty County, Georgia) did not exhibit typical defensive behavior or try to escape when prodded, but instead hid its head beneath its coiled body and remained in this position for over a minute. Slow movements or an inability to mount a typical defensive posture may leave surface-active *C. adamanteus* vulnerable to predation.

I thank Terry Norton, Beth Willis-Stevenson, Tommy Hilliard, Jeff Humphries, and W. H. Martin for help with this note.

CROTALUS ADAMANTEUS (Eastern Diamondback Rattlesnake). **DIET**. In the course of nuisance snake removal and relocations in Alachua County, north central Florida (USA) during September 2000, we observed, on two separate occasions, evidence of predation on *Felis catus* (domestic house cat) by *Crotalus adamanteus*.

The first *C. adamenteus* was captured in a homeowner's front yard. The snake was ca. 130 cm. in length, and it had ingested a meal so large as to become effectively immobile. The snake was retained at our holding facility to allow the meal to be digested before relocation. Over night, the snake regurgitated a partially digested, large black house cat.

A few days later, at a different location, we captured a second *C. adamenteus* in a gopher tortoise (*Gopherus polyphemus*) burrow. This snake was also grossly engorged, and it made little attempt to escape. It also was taken to our holding facility prior to relocation. Ten days later, the snake defecated a large amount of feces containing black fur, teeth, and claws identified as belonging to *F. catus*. On a side note, the burrow where we captured the snake had, radiating away from its entrance, the first-shed skins of nine newborn *C. adamenteus*.

In the past twelve years we have noted two other possible incidents of cat predation by *C. adamenteus*. In these cases, missing pet cats and fat snakes were observed. All of these snakes were subsequently released into safer habitats.

Our thanks to Paul Moler, Wildlife Biologist, Florida Fish and Wildlife Conservation Commission, for his welcome input.

CROTALUS PRICEI (Twin-Spotted Rattlesnake). **REPRODUCTION**. On 1 September 2002, a pair of *Crotalus pricei* was observed in copulation on a shaded area of talus and soil from the Barfoot talus slide in the Chiricahua Mountains, Cochise County, Arizona, USA (31°55'09"N, 109°16'43" W, 2560 m). The air temperature was 23–24°C, and it was cloudy following recent rain. The total length of the female was ca. 46 cm; the male snake was 41 cm. The male was on top of the dorsal surface of the female with their tails obviously intertwined. The male made pulsating movements while crawling over the female. The snakes continued mating for about an hour when the flash of a camera startled the pair and the female retreated under a rock. The male immediately pursued her and quickly resurfaced about 30 cm away looking for the female. The male was apparently unaware of our presence.

Little is known about the reproductive behavior of *C. pricei*. What is known has focused primarily on the fecundity of females and the size of their offspring (Goldberg 2000. West. N. Am. Nat. 60:98–100; Lowe et al. 1986. The Venomous Reptiles of Arizona. Arizona Game and Fish Department, Phoenix, 115 pp.; Mahaney 1997. Herpetol. Rev. 28:205). Male and female *C. pricei* have been found in close proximity to each other between mid-August and mid-September (Prival 2000. Sonoran Herpetol. 13:14–18). There is one report of captives mating in summer/autumn (Schuett 1992. *In* Campbell and Brodie [eds.], Biology of the Pit Vipers. Selva, Tyler, Texas). These reports suggest that these snakes breed during the monsoon season and the females retain sperm over the winter.

We thank Dave Hardy and Gordon Schuett for helpful comments on this note.

DIPSAS CATESBYI (Catesby's Snail-eater). **PREY**. Snakes of the genus *Dipsas* are highly specialized moluscivores. Data on the diet of *Dipsas* have been reported almost exclusively for the Amazon region despite the wide occurrence of the genus in the Atlantic forest. The diet includes mollusks in general but there are also records for insects (Beebe 1946. Zoologica 31:24–25; Cunha and Nascimento 1978. Publ. Avul. Mus. Par. Emílio Goeldi 31:74). In the stomach of an individual of *D. pavonina* from Santarém, Pará, a lizard's foot was found (Martins 1999. Herpetol. Nat. Hist. 2:78–150). Here we present data on the diet of a probably isolated population of *D. catesbyi* in the Atlantic forest in the state of Bahia, Brazil. The specimens were captured in cocoa groves (Alves 2000. Biologia reprodutiva das serpentes do gênero *Dipsas* Laurenti, 1768 do sudeste da Bahia. Dissertação de Mestrado, Universidade Estadual Paulista, Botucatu, São Paulo. 106 pp.), which is traditionally cultivated under the shade of the forest in a system locally called "cabruca." All specimens are housed in the Coleção Zoológica Gregório Bondar (CZGB), of the Centro de Pesquisas do Cacau, in Ilhéus, Bahia, Brazil. An examination of the stomach of 194 specimens at different ages showed that *D. catesbyi* preys primarily on slugs ($N = 85$) rather than snails ($N = 5$). The slugs can be ingested by any extremities of their body. There is no correlation between the number of ingested prey and snout–vent length (SVL) ($r = -0.031$, $p > 0,05$) or between prey length and SVL ($r = 0.38$, $p > 0,05$). One female (470 mm SVL, 174 tail length; CZGB 5942) had a gekkonid lizard ingested headfirst; it was positioned in the anteriormost portion of the stomach near the mouth, suggesting difficulties in swallowing it. Besides the lizard we also found a leg from an orthopteran. These

are the first published data on the natural history of *D. catesbyi* from the Atlantic forest.

EPICRATES SUBFLAVUS (Jamaican Yellow Boa). **DIET**. Bat predation has been documented for *Epicrates* boids on the Caribbean islands of Cuba (Hardy 1957. Copeia 1957:151–152) and Puerto Rico (Rodriguez-Duran 1996. J. Herpetol. 30:533–536). On Jamaica, *E. subflavus* has been observed hanging from vegetation at the entrances of caves, striking at bats as they emerge at dusk, but to the best of our knowledge, no successful strike-captures have been reported in the literature for this species (Vareschi and Janetzky 1998. Jamaica Nat. 5:34–35).

On 7 April 2000, during monthly monitoring of the resident bat colony of Windsor Great Cave, Trelawny, Jamaica (18°21'N, 77°39'W, elevation 120 m), we observed a juvenile female boa (94 cm SVL, 345 g) successfully capture and swallow a Jamaican fruit bat (*Artibeus jamaicensis*). At 1700 h we hung a single-frame harp trap (1.5 x 1.5 m^2 frame constructed of 5 cm PVC tubing, tensioned 8# nylon monofilament strung at 25 mm spacing) at the lower entrance of Windsor Great Cave. Bats began emerging from the cave at 1820 h and the first bat was captured in the trap at 1835 h. The bat colony of Windsor Great Cave includes: *Pteronotus parnellii* (forearm 54 mm, 14 g), *P. macleayii* (forearm 39 mm, 7 g), *P. quadridens* (forearm 44 mm, 8 g), *Mormoops blainvillii* (forearm 45 mm, 10 g), *Macrotus waterhousii* (forearm 55 mm, 20 g), *Glossophaga soricina* (forearm 38 mm, 11 g), *Monophyllus redmani* (forearm 40 mm, 13 g), *Artibeus jamaicensis* (forearm 60 mm, 52 g), *Erophylla sezekorni* (forearm 48 mm, 16 g), and *Tadarida brasiliensis* (forearm 41, 10 g) (unpubl. data). The total bat population is estimated to be 50,000–100,000 (Vogel 1997. Report to NRCA).

At 1915 h, we noticed a boa hanging from a medium-sized liana at the upper portion of the cave opening. The boa's body position was similar to what other researchers, who have observed this phenomenon, have described: her tail was coiled around the vine and about two thirds of her body length was hanging down, with a slight S-shape. Her ventral surface faced inwards to the cave chamber. As the stream of bats flew past, the boa struck, with mouth agape, at those bats that appeared to make contact with her. At 1925 h we approached the cave entrance to remove the harp trap and, at 1930 h, while continuing to remove bats from the trap's holding bag, we heard a "squeak," signaling the successful capture of a bat by the boa. We did not observe the actual strike. We removed the catch bag from the harp trap to enable any additionally-captured bats a means of escape, and repositioned ourselves 4 m from the cave entrance to observe the snake's manipulation of her prey. We used dimmed headlamps and periodic photographic flashbulbs to record the events, which did not appear to disturb the snake.

The boa maintained constriction for ca. 4 min. She then relaxed her coils while grasping the bat by its neck in order to re-orient the body for head-first ingestion (Fig. 1). The wings of the bat, which splayed outwards from the shoulders, clearly made intraoral transport difficult. The snake spent ca. 35 min. working her head over the bat before she was able to close her mouth completely. The final positioning of the bat's body and appendages as the snake completed oral manipulation was: left wing and head, body, and right wing trailing with the rump. After closing her mouth, the boa coiled her body three times and slid her head and neck up through her coils to assist in pushing the meal towards her digestive tract.

At 2025 h we captured the boa for further observation. The following morning, 10 April 0800 h, the "bat bulge" was visible half way down the length of her body. On 15 April 0800 h, we collected a fecal pellet, which contained numerous mammal hairs. We completed collecting morphometric data, which included weight at time of capture (365 g), weight after passing fecal pellet (345 g), weight of fecal pellet (20 g), skull length (34.8 mm), and skull width (26.5 mm). Using photointerpretation techniques, we used the dimensions of the boa's skull to estimate the length of the bat's forearm (ca. 55–60 mm). Forearm length, coupled with the weight of the fecal pellet, the bat's facial features and reduced interfemoral membrane, lead us to identify the bat as *Artibeus jamaicensis*. The thoracic cavity of a live, adult *A. jamaicensis* measures 37 x 25 mm (dorso-ventrally compressed).

After permanently marking the boa with caudal scale clipping, we returned her to the capture site on 16 April 1930 h. We have continued with one-night-per-month trapping of bats at the cave entrance and on 26 May 2001 captured another juvenile female boa (85 cm SVL, 195 g), which had positioned herself on the top bar of the harp trap. We have also observed juvenile boas at Windsor Great Cave on two previous occasions. On 19 July 1999 2300 h, SK captured, marked, and released a juvenile female (92 cm SVL, 395 g) found on the ground at a larger, upper opening of the cave. In 1996 MS observed a small boa in the rear of the first cave chamber, approaching the second chamber, where one of the bat

FIG. 1. Following constriction, a juvenile female *Epicrates subflavus* re-orients a Jamaican fruit bat (*Artibeus jamaicensis*) for head-first consumption.

roosts is located.

It is interesting to note that the boas that others and we have observed at Windsor Great Cave have all been relatively small animals. We have encountered larger adults in the Windsor environs (e.g., female, 148 cm SVL, 2000 g), but hunting for bats appears restricted to juveniles. Whether this is because of physical constraints of the hunting perch (Chandler and Tolson 1990. J. Herpetol. 24:151–157), the imposition gravity poses to blood circulation when larger snakes hang vertically (Lillywhite and Henderson 1993. *In* Siegel and Collins [eds.], Snakes: Ecology and Behavior, pp. 1–48, McGraw-Hill, New York), or because the bats represent low- or marginal-energy prey items for adult snakes, particularly as they weigh less than predicted for their maximum diameter because of their protruding wings (Cundall and Greene 2002. *In* K. Schwenk [ed.], Feeding: Form, Function, and Evolution in Tetrapod Vertebrates, pp. 293–332. Academic Press, San Diego, California), is unknown. While the large bat roost of Windsor Great Cave represents a predictable, high density but localized prey resource, we still lack information on hunting success under natural conditions, when a trap is not in place that disrupts the bats' flight. Prior and Gibson (1997. Herpetol. Rev. 28:72–73) recorded > 200 unsuccessful strikes by a juvenile *E. subflavus* during a period of 1 h 45 min. Research into the energetic costs and benefits of opportunistic bat predation would improve our very limited understanding of the foraging ecology of Jamaica's endemic boa as well as ensure adequate protection for critical habitat and food resources of this vulnerable snake.

The bat research that "assisted" the boa was supported by a student scholarship to S. Koenig from Bat Conservation International and additional funding from the Jamaica Conservation and Development Trust. Research was conducted under Natural Resources Conservation Authority permit Ref No. 18/47. We thank Harry W. Greene for his helpful comments, particularly on prey types and gape diameters in snakes.

Submitted by **SUSAN E. KOENIG** and **MICHAEL SCHWARTZ**, Windsor Research Centre, Sherwood Content P.O., Trelawny, Jamaica (e-mail [SK]: susankoenig@cockpitcountry.com; [MS]: michaelschwartz@cockpitcountry.com).

LAMPROPELTIS GETULA NIGRA (Black Kingsnake). **MAXIMUM SIZE.** The maximum size record reported for *Lampropeltis getula nigra* by Conant and Collins (1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.) is 58 in (147.3 cm). On 4 July 1999 a recent DOR specimen was collected by Brainard Palmer-Ball near the Franklin School in Washington County, Indiana, USA. ca. 2.2 km N of Blue River (38°32.7'N, 85°56.3'W). Before preservation, this large male specimen measured 1480 mm in total length. Additional morphometric and meristic data are as follows: snout–vent length 1309 mm, tail length 171 mm, ventrals 203, and caudals 48. This specimen is deposited in the vertebrate collections at Morehead State University (R4682). Examination of 27 additional male *L. g. nigra* from Kentucky gave the following ranges and mean values: total length 736–1211 mm (mean 981.9 mm); snout–vent length 654–786.7 mm (mean 675 mm); tail length 158–188.7 mm (mean 176 mm); ventrals 198–213 (mean 205.9); and caudals 41–57 (mean 49.6) (Meade 1993. Kentucky Snakes: Their Systematics, Variation and Distribution. Ph.D. dissertation, Univ. of Southern Mississippi, Hattiesburg, Mississippi. 609 pp.).

Submitted by **LES MEADE**, Morehead State University, Morehead, Kentucky 40351, USA (e-mail: l.meade@morehead-st.edu) and **BRAINARD PALMER-BALL**, Kentucky State Nature Preserves Commission, 801 Schenkel Lane, Frankfort, Kentucky 40601, USA; e-mail: brainard.palmer-ball@mail.state.ky.us.

MASTICOPHIS BILINEATUS (Sonoran Whipsnake). **PREY.** *Masticophis bilineatus* is generally regarded as a generalist forager, and snakes occasionally are reported as food items (e.g., Grismer 2002. Amphibians and Reptiles of Baja California, Including its Pacific Islands and the Islands in the Sea of Cortés. Univ. California Press, Berkeley, California. 399 pp.). A study by Camper and Dixon (2000. Texas J. Sci. 52:83–92) found no snakes in the stomachs of 335 *M. bilineatus*, but Enderson (1999. Sonoran Herpetol. 12:72–73) reported the predation of a neonate *Crotalus molossus* by a very large (1679 mm) specimen. Klauber (1972. Rattlesnakes. Univ. California Press, Berkeley, California, p. 1105) also relates a story of an adult *M. bilineatus* consuming a *C. molossus*. Here, I document a snake species not previously observed as prey for *M. bilineatus*.

On 20 August 2002, while at Peck Canyon in southern Arizona (31°29'N, 111°04'W) at 1300 h, I observed an adult *M. bilineatus* (ca. 100 cm SVL) consuming a smaller *Salvadora hexalepis* (Fig. 1). I did not attempt to separate the two snakes, but estimate the size of the *Salvadora* to be ca. 40–55 cm in total length. The *Salvadora* was being swallowed headfirst, and was approximately two-thirds consumed when I first found the snakes. I watched and photographed the snakes for ca. 10 minutes before leaving. During that time period neither snake moved; it appeared that the

FIG. 1. *Masticophis bilineatus* consuming *Salvadora hexalepis*.

Masticophis was aware of my presence, and the *Salvadora* may have already been dead. This record is the first documentation of *S. hexalepis* in the diet of *M. bilineatus*. The ambient shaded air temperature was ca. 35°C at 1 m off the ground, cloud cover was less than 10%, and the ground was saturated from recent rains. A voucher slide has been accessioned at the University of Arizona Collection of Amphibians and Reptiles (UAZ 54678-PSV).

Submitted by **ERIC W. STITT**, School of Renewable Natural Resources, 125 Biological Sciences East, University of Arizona, Tucson, Arizona 85721, USA; e-mail: estitt@u.arizona.edu.

MASTICOPHIS FLAGELLUM (Coachwhip). **PREY.** The diet of the diurnally active, swift-moving *Masticophis flagellum* includes rodents, birds and their eggs, a variety of lizards, young turtles, some insects, and also snakes (e.g., Stebbins 1985. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts). Beaman and Harris (2002. Herpetol. Rev. 33:214–215) recently summarized seven species of snakes previously reported as prey of *M. flagellum*, as well as their own account of a gopher snake (*Pituophis catenifer*) as prey. Herein, I report another incidence of *P. catenifer* being eaten by *M. flagellum*. On 30 August 2002 at 1230 h, while conducting a rare plant survey in a Sonoran desertscrub/semidesert grassland habitat, I chanced upon a *P. catenifer* being eaten by a black-phased *M. flagellum*. The observation took place on Tohono O'odham Nation, San Xavier District lands leased by ASARCO Inc., about 21 km SW of downtown Tucson in Pima County, Arizona, USA (32.021547°N, -111.039105°W). The *P. catenifer* was the first to be observed. It was located next to a clump of bush muhly (*Muhlenbergia porteri*), and the snake appeared undisturbed at my presence. Upon closer inspection, I noticed that a *M. flagellum* had hold of the *P. catenifer* and that it had been swallowed headfirst slightly more than halfway. The *M. flagellum* was loosely coiled and fully shaded from the overhead sun by the grass cover, while the portion of the *P. catenifer* not yet swallowed was completely exposed to the sun on the western-side of the grass cover. Soon after the encounter the ambient air temperature (taken at 1 m with a Shultheis-type thermometer) was 38.1°C, and the ground temperature beneath the *M. flagellum* in the shade was 33.8°C and 42.2°C under the exposed *P. catenifer*. I inadvertently disturbed the snake when taking the temperature beneath its coil and it proceeded to regurgitate the partly digested *P. catenifer*, with only the gopher snake's mid- and tail sections being recognizable. It was not known exactly how long the *M. flagellum* had hold of its prey, but the *P. catenifer* was discolored and internally yielding, which indicated the onset of autolysis. I did not disturb the *M. flagellum* any further and it remained beneath the clump of grass, briefly shaking its tail as I departed. Because I did not try to catch the *M. flagellum*, I could only estimate its total length at ca. 110 cm. The *P. catenifer* being partially eaten was more difficult to gauge but appeared to have been about the same size as the *M. flagellum*. The two snakes were photographed as the one was consuming the other and a color slide was deposited in the University of Arizona herpetological collection (currently uncatalogued).

MICRURUS FULVIUS TENER (Texas Coral Snake). **DIET**. The diet of *M. fulvius* generally consists of small lizards and snakes (Greene 1984. Univ. of Kansas Mus. of Nat. Hist. Spec. Publ. 10:147–162). On 20 October 2001 a female *M. f. tener* (SVL 734 mm; weight 64 g) was captured on the Griffith League Ranch in Bastrop County, Texas, USA. The snake was taken to the lab for measurements. During transport, the snake regurgitated a male *Masticophis flagellum* (SVL 476.3 mm; weight 32 g) and died. The *M. flagellum* was 64.9% of the *M. f. tener*'s length and 50% of its weight, which is slightly higher than the mean body mass relationship for coral snakes and their prey determined by Greene (*op. cit.*). There are few records of coral snakes eating larger colubrids (Neill 1968. Florida Wildlife 21:22–25; Greene, *op. cit.*), and we were unable to locate references to *M. flagellum* being eaten by *M. fulvius*. Both were deposited in the Texas Wildlife Cooperative Museum at Texas A & M University (*Micrurus*: TCWC84720; *Masticophis*: TCWC84719).

We thank Rob Bryson and Jeff Mink for their assistance capturing the snake, and Martha Dollar for expediting the delivery of Greene's paper.

MICRURUS STEWARTI (Panamanian Coral Snake). **COLOR VARIATION**. Color patterns in snakes of the genus *Micrurus* are relevant for comprehending coral snake mimicry systems (e.g., Greene and McDiarmid 1981. Science 213:1207–1212), and for an adequate identification of these potentially harmful snakes.

On 23 January 2002, at night, FAS and RID found an adult male *M. stewarti* (619 mm TL, 531 SVL) active on the ground along the margins of a stream at Quebrada Peñalosa, Cuatro Callitas, Distrito de Donoso, Provincia de Colón (ca. 8°58'0.86"N, 80°33'9.16"W, 40 m elev.), within a stream reach flowing through a mixture of forest and humanly disturbed areas. The snake was essentially bicolored black and white, having a white head with a black snout, a rather long black nuchal ring, and a series of alternating white and black rings throughout the body and tail. The black rings were more than twice the length of the white rings. The white rings have a very faint pinkish tint, somewhat more noticeable on the head and first two body rings, and dorsally with black tipped scales. The specimen was collected and tagged, Círculo Herpetológico de Panamá (CH 5348), and later deposited in the Museo de Vertebrados de la Universidad de Panamá (MVUP 1797).

M. stewarti is a poorly known, rare species (Roze 1996. Coral Snakes of the Americas, Krieger Publishing Co., Malabar, Florida). No specimens of this species were known to have the exclusively black and white coloration reported herein, being previously regarded as a bicolor snake with black and red rings (Campbell and Lamar 1986. The Venomous Reptiles of Latin America, Comstock Publishing Associates, Ithaca, New York; Roze 1996, *op. cit.*). In addition, we have observed 8 live specimens of *M.*

stewarti from other localities in central Panamá, all of them having black and bright red rings. Therefore, in this species, the black and white ringed color variant is present in a low frequency.

In central Panamá, two other species of bicolored coral snakes occur in sympatry with *M. stewarti: M. multifasciatus*, also with black and red rings, and *M. mipartitus* with black and white body rings, the white color replaced by orange red on the head and tail (Campbell and Lamar 1986, *op. cit.*; Roze 1996, *op. cit.*; pers. obs.). Hence, the black and white ringed color variation, observed in *M. stewarti*, conforms to the geographic concordance in color pattern expected among presumed coral snake models as Müllerian mimics.

The reported observation was made during the project "Recopilación y Presentación de Datos de Recursos Ambientales y Culturales en la Región Occidental de la Cuenca del Canal de Panamá," funded by the Autoridad del Canal de Panamá, and performed by The Louis Berger Group Inc., Universidad de Panamá and Smithsonian Tropical Research Institute consortium.

NERODIA SIPEDON SIPEDON (Northern Watersnake). **DIET**. On 15 July 2001, while conducting a herpetological survey of Shenandoah National Park, Virginia, USA (Research Permit number: SHEN-2001-SCI-0005), we captured a female *N. sipedon* (350 mm SVL, 103 mm TL, 31g) at coordinates 38°14'26"N; 78°41'24"W (NAD 27) that regurgitated a larval *Gyrinophilus porphyriticus* (74 mm SVL, 50 mm TL, 8.25 g) upon capture. Habitat consists of mixed deciduous woodland on Doyle's River with a two-step cascade of water 8.5 m high, the animal being found in a rocky pool at the bottom of the waterfall. This is the second documentation of predation on *G. porphyriticus* by *N. sipedon* (Uhler et al. 1939. Trans. 4th North Am. Wildl. Conf. 1939:605–622). Prey body mass accounted for 26.6% of the predator's body mass. The larval salamander was consumed head-first and was still alive upon being regurgitated by the snake. Our observations provide the first predator-prey morphometric and orientation data on these two species. We thank Boripat Siriaroonrat and Shelley C. Hickman for field assistance and logistical support during the survey.

PORTHIDIUM NASUTUM (Hog-nosed Pitviper). **PREY**. *Porthidium nasutum* ranges from southern Mexico to Ecuador and has been documented to feed on a variety of vertebrates. Prey items of *P. nasutum* include species of birds, rodents, lizards, and anurans (Greene 1997. Snakes: The Evolution of Mystery in Nature. University of California Press, California, 351 pp.; Alvarez del Toro 1983. Los Reptiles de Chiapas, 3rd ed. Instituto de Historia Natural, Tuxtla Gutierrez, Chiapas, Mexico, 248 pp.). Juveniles are also known to feed on a variety of invertebrates (Campbell 1998. Amphibians and Reptiles of Northern Guatemala, the Yucatan, and Belize. University of Oklahoma Press, Norman, Oklahoma, 380 pp.). However, detailed accounts of most prey items of *P. nasutum* are lacking. We report an anuran prey item of *P. nasutum* that has not been previously documented.

On 18 May 1998, we encountered a *Porthidium nasutum* on the side of the western trail (Sendero Occidental) at trail marker 50 at La Selva Biological Station, Costa Rica (2015 h). We observed the snake for ca. 30 minutes and left. One of us (DAW) returned to the same location 1 h later with a camera and discovered a dead *Rana warszewitschii* next to the snake. This observation suggests that the snake struck and envenomated the frog and then released it. After watching for about 5 minutes, the snake began to ingest the frog. Approximately 30 minutes later, the snake moved deeper into the forest with the frog half way in its mouth.

We thank H. Greene and C. Guyer for encouraging us to publish our observation, and C. Guyer for identifying the *Rana warszewitschii* from photographs. Thanks to J. Raich and O. Rocha for giving us the opportunity to study in Costa Rica.

PTYAS CARINATUS (Keeled Rat Snake) **PREY.** There are few data available on the feeding habits of *Ptyas carinatus* in the tropical forests of Southeast Asia (Cox 1991. The Snakes of Thailand and Their Husbandry. Krieger Publishing, Malabar, Florida. 564 pp.). On 10 July 2001 (1100 h) along the trail from Kampung Mukut to Sungai Raya on Pulau Tioman, West Malaysia, a juvenile *P. carinatus* was observed eating a juvenile *Gongylosoma* sp. The habitat was coastal forest (Latiff et al. 1999. Raffles Bull. Zool. 6:11–72) with dense leaf litter. Immediately after the sighting, the *Gongylosoma* sp. was released and both snakes fled. The *Gongylosoma* sp. had bite marks on its body from the attack. Both snakes were captured, preserved, and deposited in the Zoological Reference Collection (ZRC) of the National University of Singapore; *Ptyas carinatus* (ZRC 2.5142), *Gongylosoma* sp. (ZRC 2.5143).

RHINOBOTHRYUM BOVALLII (Coral Cat-eyed Snake). **SIZE.** The maximum total body length reported for *Rhinobothryum bovallii* is 130.2 cm (Wilson and Meyer 1985. The Snakes of Honduras. Milwaukee Publ. Mus., Publ. Biol. Geol. 6, 159 pp.). Here I report a male *R . bovallii* from Costa Rica with a total body length of 176.2 cm (135.0 cm SVL, 41.2 cm tail length). The specimen, University of Costa Rica Museum of Zoology (UCR-14916), was captured by Miguel and Norberto Solano in Guayacán de Siquirres, Limón province (northeastern Caribbean versant) on the night of 14 December 1997, while moving slowly on the floor in primary rainforest.

I thank Louis W. Porras and William W. Lamar for comments on this note, and Federico Bolaños and Gerardo Chaves for allowing me to examine specimens at the School of Biology and Museum of Zoology at the University of Costa Rica.

THAMNODYNASTES STRIGATUS (Corredeira). **DIET**. Amphibians have been reported as prey of *T. strigatus* (Cei 1993. Mon. XIV Boll. Mus. Reg. Sci. Nat. Torino, 949 pp.; Achaval and Olmos 1997. Anfibios y Reptiles del Uruguai. Série Fauna N°1, 128 pp.; Marques et al. 2001. Serpentes da Mata Atlântica: Guia ilustrado para a Serra do Mar. Holos Ed., 184 pp.). However, the specific amphibian species have not been reported.

On 9 March 2000, we collected three *T. strigatus,* on the eastern bank of the Uruguai River (28°23'43"S, 52°29'59"W), near the municipality of Itá, in the State of Santa Catarina, Brazil. One specimen (CEPB/NAT 2848; male SVL 546.3 mm) contained the posterior limbs of a specimen of *Odontophrynus americanus* (tibia: 23.0 mm; tarsus: 18.6 mm). The second specimen (CEPB/NAT 2497; female SVL 668.5 mm) contained most of the posterior limbs and pelvic region of a specimen of *Hyla faber* (femur: 40.5 mm; tibia: 46.7 mm; tarsus: 29.9 mm). The third specimen (CEPB/NAT 2469; female SVL 630.3 mm) contained the posterior limbs of a specimen of *Rana catesbeiana* (tibia: 37.2 mm; tarsus: 17.6 mm). Our observations include three families of amphibians in the diet of *T. strigatus*. The snakes and their respective stomach contents are deposited in the Herpetological Collection of the Centro de Estudos e Pesquisas Biológicas, at the Catholic University, Goiânia, Goiás, Brazil.

THAMNOPHIS SIRTALIS SIRTALIS (Eastern Garter Snake). **PREDATION**. On 26 April 2001 in Lake Creek (T16S, R2W, Sec. 13, SW1/4 of NE1/4, Cache, Illinois USGS 7.5' topographic map) Alexander Co., Illinois, USA, one of us (WJP) observed a *Thamnophis s. sirtalis* being carried in the mouth of a gar, *Lepisosteus* sp. (either *L. platostomus*, shortnose gar, or *L. oculatus*, spotted gar) with a portion of the snake's body floating at the surface of the water. The gar swam with the snake for several minutes under and near the State Route 3 bridge before the snake was hooked using a fishing pole and forcibly taken from the fish. The snake was dead but in good condition and measured 621 mm TL. The attack on the snake was not observed. Gars were abundant in the stream and were seen cruising just below the surface of the water. Four gars caught by hook and line and many others observed that day were all *L. platostomus*.

A spotted gar was reported to have eaten a small turtle, *Sternotherus odoratus*, in Missouri (Redmond 1964. Ecology of the Spotted Gar [*Lepisosteus oculatus* Winchell] in southeastern Missouri. M.A. thesis. Univ. Missouri. viii + 115 pp.). Additionally, *T. sirtalis* has been reported in the diet of largemouth bass, *Micropterus salmoides* (Knapik and Hodgson. 1986. Herpetol. Rev. 17:22). However, this is the first report of *T. sirtalis* or any snake being preyed on by any species of gar. The snake is deposited at the Illinois Natural History Survey (INHS 17214).

THAMNOPHIS SIRTALIS SIRTALIS (Eastern Garter Snake) and ***PLETHODON ALBAGULA*** (Western Slimy Salamander). **PREDATION**. *Thamnophis sirtalis sirtalis* is a generalized feeder predating mostly on earthworms and amphibians (Uhler et al. 1939. Trans. North Am. Wildl. Conf. 4:605–622). Salamanders (*Ambystoma, Desmognathus, Eurycea, Necturus, Notophthalmus,* and *Plethodon*) are among the most frequently consumed amphibian prey (Ernst and Barbour 1989. Snakes of Eastern North America. George Mason Univ. Press, Fairfax, Virginia. 282 pp.). Herein, we describe, for the first time, predation by *T. s. sirtalis* on *Plethodon albagula* from a mine shaft in Arkansas.

We observed a female *T. s. sirtalis* on 11 August 2002 while investigating the nesting ecology of *P. albagula* in an abandoned mine shaft. The mine shaft (Spillway Mine) is a nesting sanctuary for this salamander species; it is located near Blakely Mountain Dam of Lake Ouachita (Garland County) in the Ouachita National Forest of south-central Arkansas. The shaft extends ca. 190 m horizontally into a moderately sloping, rocky hillside. We collected the active garter snake inside the mine shaft at ca. 2.5 m from the mouth of the shaft.

The snake measured 395 mm SVL and 136 mm tail length. Upon necropsy, the snake contained a mostly-digested *P. albagula* in its stomach. It appeared that the salamander had been ingested tail first. We were unable, however, to determine the age or sex of the prey item because of the degree of digestion. We deposited the snake in the Arkansas State University herpetological museum collection (ASUMZ 27218).

We thank David A. Saugey (Vertebrate Biologist, United States Forest Service) and the Army Corp of Engineers for access to Spillway Mine, and Sigma Xi Grants-in-Aid (to RRK) for research funding.

cussed in Schuett (1992) and Aldridge and Duvall (2002).

This population of *C. polystictus* lies within an artificial, highly-modified habitat. Such an area may provide an increase in prey availability because of high rodent densities typically associated with agricultural areas. Several of the scats from wild collected individuals examined in the lab contained rodent hair (species not identified). Specimens were most commonly encountered near heavily vegetated earthen canals and berms. The monoculture created by hectares of uninterrupted cornfields contain unsuitable habitat, and thus concentrate populations of *C. polystictus* along breaks in their periphery. The use of agricultural chemicals and pesticides and conversion of earthen canals to concrete canals may negatively affect this population. Searches near concrete canals failed to produce any specimens of *C. polystictus*, presumably because of their lack of rodent burrows and vegetated sides. Although this population of *C. polystictus* appears to be healthy, it should be considered fragile because of its location in an area subject to further modification for agriculture.

Acknowledgments.—We thank A. Kardon, K. Peterson, and J. Galvan for their assistance. J. Mueller, J. Dixon, M. Dorcas, and an anonymous reviewer reviewed the manuscript and provided additional comments. Research and collecting were conducted under the authority of SEMARNAT scientific research permit OFICIO NÚM/SGPA/DGVS/3394 issued to RWB.

The need for conservation and management of rare species is becoming increasingly important as wildlife species and their habitat continue to decline. Translocation of wild captured adults to augment and reintroduce populations has been successfully used for some endangered avian species (see Carrie et al. 1999; Rudolph et al. 1992). In general, success rates for mammals and birds are higher than those for amphibians and reptiles (Dodd and Seigel 1991; Griffith et al. 1989).

The Timber Rattlesnake (*Crotalus horridus*) is listed as a State of Texas threatened species and translocation of captive raised snakes might benefit small populations. Controversy exists on the benefits versus problems associated with translocation of amphibians and reptiles (Burke 1991; Dodd and Seigel 1991; Reinert 1991). A recent evaluation of the impacts of translocation on behavior and survival of mature *C. horridus* suggests that translocation of adult snakes not be recommended as a standard management technique because of immediate aberrant movement behavior patterns and long-term elevated rates of overwinter mortality, predation, and disease (Reinert and Rupert 1999).

Because of the problems associated with translocation of adult *C. horridus*, the ability to successfully raise neonate rattlesnakes and successfully introduce them into forest habitat may be an essential conservation technique if viable populations of this rare species are to be maintained in the wild. If captive-raised neonates can be grown to sufficient size, predation-related and overwinter mortality events suffered by neonates and first-year juveniles might be minimized, increasing the net survival rates of cohorts released to the wild.

We captive raised one neonate *C. horridus* in 1993–1994 and eight in 1994–1995, recording detailed growth data on the eight snakes over an 11-month period. The nine snakes were released with surgically implanted transmitters in eastern Texas and we monitored their movements for six years. We determined their survival rates in the wild to evaluate the possible merit of using captive-raised neonates to augment small, isolated populations.

Materials and Methods.—Locations of released *Crotalus horridus* with transmitters were monitored in the Stephen F. Austin Experimental Forest, southern Nacogdoches County (31°29'N,

94°47'W), in eastern Texas. Bottomland hardwood forest comprises 728 ha of this 1038-ha experimental forest and pine uplands the remaining 310 ha. Approximately 670 ha of the bottomland hardwood forest are in the Angelina River flood plain. Minimal timber harvesting has occurred on this forest and canopy trees in both the bottoms and uplands are 70+ years old.

On 30 August 1994 eight neonate *C. horridus* (6 females and 2 males) were obtained from the brood of a telemetered adult female from the Loco Bayou Hunt Club 8 km west of the experimental forest. The neonates were obtained prior to their first ecdysis as they crawled around the entrance to a nine-banded armadillo (*Dasypus novemcinctus*) burrow. The eight neonate rattlesnakes were individually housed in 27 x 29 x 56 cm herpetological cages with clear Lucite sliding fronts, an electric heating pad under the cage, and a rock to assist shedding. Water in a petri dish was always present. Between 31 August 1994 and 17 July 1995 live mice (*Mus musculus*) were offered weekly to the rattlesnakes in an attempt to maximize their growth. From a management perspective, our objective was to get the neonates to a near-adult size as quickly as possible to enhance their probability of survival when released in the wild. During the first two months mice < 18 g were offered to the neonates; thereafter, a range of mice between 10 and 35 g were offered and taken by the snakes. Mice and rattlesnakes were weighed prior to feeding and the weight of each mouse killed and consumed by each snake was recorded. Snake mass, snout–vent length (SVL), and total length were measured initially and then monthly over the next 10 months (last measurement 17 July 1995).

On 17 July 1995 four *Crotalus horridus* (three females and one male) were selected for subcutaneous implantation of a 10.3 g Holohil® SI-2T radiotelemetry transmitter using the technique of Weatherhead and Anderka (1984) and, following at least a one week recovery period, were released together in bottomland hardwood forest on the Stephen F. Austin Experimental Forest on 4 August 1995. The remaining male and three females received a subcutaneous transmitter on 27 February 1996 and were released together at the same location as the initial four snakes on the experimental forest on 13 March 1996. Earlier, an additional female neonate (which weighed 35 g upon capture on 16 September 1993 near Bingham Lake, Tyler County, Texas, on the Forest Lake Experimental Forest and was captive-raised to a weight of 246.7 g) received a transmitter on 5 March 1994 and was released in the experimental forest on 21 March 1994 at a point 100 m ENE of the location where the other eight neonates were released. During periods when snakes were not in hibernacula they were radiotracked and relocated approximately weekly using a Telonics receiver (TR-2, 150-152 MHz) with a two-element Yagi directional antenna.

Locations of all released snakes were determined weekly until they settled in hibernacula in late November. Weekly relocation commenced again in March when rattlesnakes emerged from hibernacula. Thus, post-release movements of nine captive-raised rattlesnakes were monitored from mid-March to late November over a period between four and six years. Mortality of released rattlesnakes was assumed if bones and a transmitter were found together. Dead snakes with transmitters recovered on or immediately next to a road with obvious injuries were assume to be road mortalities.

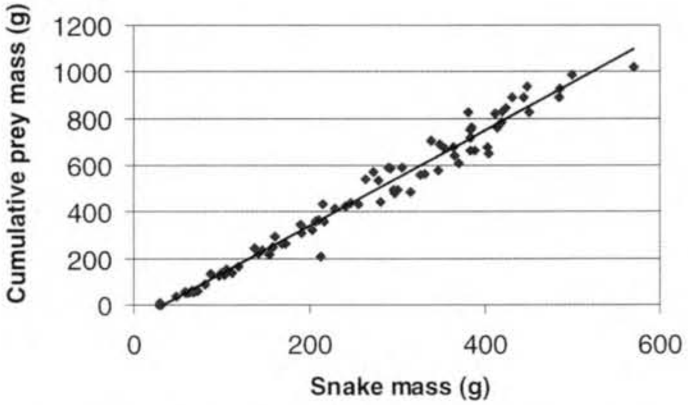

FIG. 1. Cumulative prey mass consumed by eight captive-raised neonate *Crotalus horridus* from eastern Texas versus snake mass as neonates grew (monthly measurements) over a 10-month period. The line within plotted points reflects a regression trend line ($Y = 2.0416X - 66.516$, $R^2 = 0.98$).

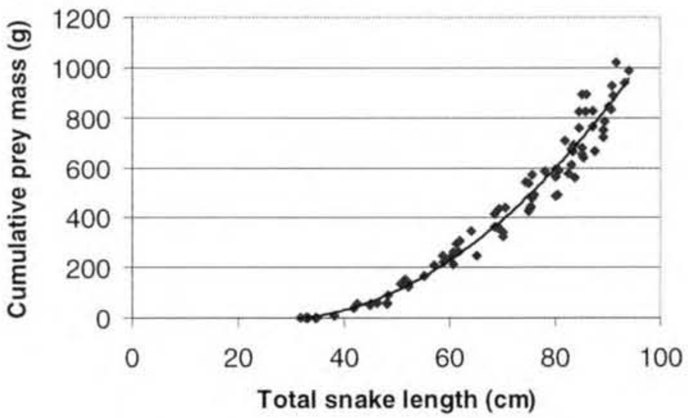

FIG. 2. Cumulative prey mass consumed by eight captive-raised neonate *Crotalus horridus* from eastern Texas versus total snake length as neonates grew (monthly measurements) over a 10-month period. The line within plotted points reflects a second-order polynomial trend line ($Y = 0.0021X^2 - 1.1265X + 142.04$, $R^2 = 0.97$).

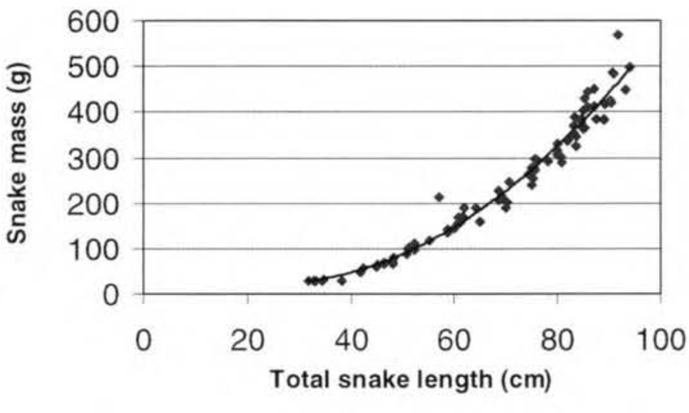

FIG. 3. Mass versus total length of eight captive-raised neonate *Crotalus horridus* from eastern Texas as neonates grew (monthly measurements) over a 10-month period. The line within plotted points reflects a second-order polynomial trend line ($Y = 0.0957X^2 - 4.5229X + 75.063$, $R^2 = 0.97$).

TABLE 1. Post-release survival of ad-lib fed neonate *Crotalus horridus* in eastern Texas. Minimum surviving rattlesnakes were those remaining in the experimental forest study area with functional transmitters. Maximum surviving includes minimum surviving plus those rattlesnakes of unknown status that dispersed from the study area or experienced transmitter failure. M = male, F = female.

Post release	Minimum surviving		Maximum surviving	
survival (y)	No. (M/F)	%	No. (M/F)	%
0	9 (7/2)	100.0	9 (7/2)	100.0
1	8 (6/2)	88.9	8 (6/2)	88.9
2	4 (3/1)	44.4	7 (5/1)	77.7
3	4 (3/1)	44.4	7 (5/1)	77.7
4	3 (2/1)	33.3	7 (5/1)	77.7
5	3 (2/1)	33.3	6 (5/1)	66.6
6	2 (1/1)	22.2	5 (4/1)	55.6

We used the program CALHOME (Kie 1994) to calculate annual minimum convex polygon (Mohr 1947) activity ranges and annual maximum distance between relocation points for nine released rattlesnakes during the first full tracking year after release, the second full tracking year after release, and all tracking years after the first full year of release.

Results and Discussion.—Captive, neonate *Crotalus horridus* initially averaged (mean ± SD) 28.7 ± 0.74 g, SVL 30.9 ± 0.97 cm, and total length 33.2 ± 0.98 cm. During the year of captivity the neonates consumed an average of 873.5 ± 113.5 g of prey mass (mice) per snake and attained an average mass of 461.8 ± 54.8 g, SVL of 81.7 ± 3.1 cm, and total length of 88.3 ± 3.4 cm (Figs. 1, 2). On average, for every 1.0 g of prey mass consumed the snakes increased their body mass by 0.48 g and their total length by 0.063 cm (Fig. 3). Following their first post parturition shed, the captive-raised neonates shed four times prior to release. Ecdysis occurred approximately every time the snakes doubled their body mass.

Eight of the nine captive-raised neonates released in the wild with surgically implanted radio transmitters survived at least one full year after their release (Table 1). A female released March 1996 survived 4 months and a male released August 1995 survived 12 months in the wild, but both were killed in road-related mortality. A female released March 1996 died or lost her transmitter (unknown cause—transmitter found in hibernaculum) two years post-release. The status of three snakes is unknown because of dispersal from our study area or transmitter failure at one, two, and three years post-release, respectively. We strongly suspect that these snakes moved out of our study area because the weekly movement of these three snakes suggested that they were shifting the center of their activity toward the west on private lands. Three of nine captive-raised neonates were known to be alive and had entered the breeding population five years post-release (Table 1). These three snakes (a female released March 1994, a female released August 1995, and a male released March 1996) were observed copulating or participating in precopulatory behavior with wild conspecifics. Although sample size is too small to detect a statistical relationship, neither month of release (March versus August) nor sex appeared to be related to death, dispersal, or survival.

During the first full tracking year after release our captive-raised rattlesnakes averaged (mean ± SD) an annual minimum convex polygon activity range of 12.10 ± 9.61 ha and a maximum distance between relocation points of 0.97 ± 0.69 km. During the second full tracking year after release the activity range was 22.01 ± 29.95 ha and maximum distance between relocation points 0.82 ± 0.06 km suggesting that activity area increased but maximum movement distance decreased slightly. For rattlesnakes that remained alive after the second full tracking year, activity area averaged 7.26 ± 4.96 ha and maximum distance between points 0.51 ± 0.16 km for all subsequent years.

Captive-raised neonate *Crotalus horridus* gained 0.48 ± 0.04 g of body mass for every 1.0 g of prey consumed. Jauch (1993) observed a higher (0.58 g) mass gain per 1.0 g prey in captive-born Puff Adders (*Bitis arietans*) that were offered mice every 2–3 weeks. However, our captive-raised *C. horridus* gained 0.063 ± 0.012 cm in total length for every 1.0 g of prey consumed, whereas Jacobsen (1986), who provided white mice and later white rats every 1–3 weeks, measured only 0.018 cm gain in total length per 1.0 g prey consumed in captive *B. arietans*. Similar to our observations with *C. horridus*, ecdysis occurred in *B. arietans* approximately every time they doubled their body mass (Jauch 1993).

Our captive-raised neonate *C. horridus* attained an average total length of nearly 90 cm prior to release in the wild. Although inexperienced in the wild, the size of these snakes after one year of *ad libitum* food in captivity would likely offset some of the predation-related mortality incurred typically by neonates during their first year. Several years would be required for wild-raised neonates to attain this size, and during these years predation rates would probably be high.

The known survival and incorporation of three (33%) of nine captive-raised neonate *C. horridus* (Table 1) into the breeding population five years post-release indicates at least some potential value of the technique to augment small populations or possibly repopulate areas where extirpation has occurred, especially if neonates were obtained through a captive breeding program. The actual survival of the captive-raised neonates may exceed 33% because the status of three additional snakes was unknown either because of long distance dispersal or transmitter failure. Some of these snakes may have moved off the study site to neighboring properties where we could no longer monitor their movements. The road mortality (two cases in which individuals were killed on blacktop roads adjacent to the experimental forest) and death in hibernaculum (one case) likely reflect what would occur in wild snakes in similar habitat (Rudolph et al. 1998). However, it is likely that unfamiliarity with habitat accounted for some of the mortality and unknown losses of snakes that we observed because the relocated snakes spent more time than typical looking for acceptable habitat, which increased the probability of predation. Charland (1989) reported a 45% overwinter mortality rate of neonate Western Rattlesnakes (*Crotalus viridis*) during their first six to eight months. Timber Rattlesnakes in eastern Texas did not seem to overwinter in communal dens, but instead typically went down a stump hole or an armadillo burrow when temperatures approached freezing. Although winters in eastern Texas are shorter in duration and milder than winters in more northern latitudes, temperatures often reach –8°C and can go as low as –18°C (Chang et al. 1996). Our captive-raised neonates avoided possibly high first-winter mor-

tality and were artificially given a boost to body mass and length well beyond what would occur in wild snakes.

Reinert and Rupert (1999) reported that 6 of 11 (54.3%) wild-captured, mature *Crotalus horridus* experienced mortality over an approximate two-year period. Three of these snakes experienced overwinter mortality, predators killed two, and one died from disease. At least 44.4% and possibly 77.7% of our neonates survived two years post-release (Table 1). The actual survival rate for our captive-raised neonates probably does not differ much from what Reinert and Rupert (1999) observed with mature rattlesnakes.

Translocated adults also exhibited higher activity and larger activity range areas than resident adult *C. horridus* (Reinert and Rupert 1999). Based on these results, they concluded that the translocation of wild-raised mature rattlesnakes to bolster diminished local populations should not be recommended as a standard conservation practice. The maximum activity ranges of our captive-raised neonates was less than 4% of the activity area observed by Reinert and Rupert (1999) for translocated adult snakes, and about 33% of the area observed for resident adults. Although our released rattlesnakes were not mature, their activity range areas did not seem to be excessive.

We do not disagree with the conclusions of Reinert and Rupert (1999) relative to the translocation of mature *Crotalus horridus*, but suggest that translocation of captive-raised neonates may be a feasible conservation technique to bolster diminished populations, particularly if captive breeding is the source of the translocated snakes.

Acknowledgments.—We thank C. R. Blem, L. Fitzgerald, and W. H. Martin for constructive comments on the manuscript. All authors had valid Texas collecting permits during the research, as well as a specific permit for the Timber Rattlesnake to capture, hold in captivity, anesthetize, implant transmitters, and release in the wild (SPR-0490-059). All appropriate Animal Care guidelines were followed (see Guidelines for Use of Live Amphibians and Reptiles in Field Research, American Society of Ichthyologists and Herpetologists; http://www.asih.org/pubs/herpcoll.html.).

The genus *Liophis* comprises about 40 species distributed throughout South and Central America, including the Caribbean (Dixon 1989, 2000). Some species present taxonomic problems or are known by a few specimens, making it difficult to establish phylogenetic relationships among them (Dixon 1987; Dixon and Markezich 1992; Donnelly and Myers 1991).

Dixon and Thomas (1985) described *Liophis atraventer* based on three specimens from Boracéia (Estação Biológica, ca. 900 m elev.), state of São Paulo, Brazil (28°38'S, 45°50'W). Dixon (1987) suggested this species is related to *L. typhlus* (Linnaeus 1758), *L. guentheri* Peracca, 1897, *L. viridis* Gunther, 1862, *L. jaegeri* (Gunther 1858), and *L. maryellenae* Dixon, 1985, which he placed in a group that encompasses the green species of *Liophis*. *Liophis atraventer* was known only by the type series until Passos and Fernandes (2001) reported a fourth specimen (MNRJ 2766) from

FIG. 1. Geographic distribution of *Liophis atraventer*. ⊙ = type locality.

Teresópolis (ca. 870 m elev.), state of Rio de Janeiro, Brazil (22°24'S, 42°57'W). During the reorganization of the herpetological collection of the Instituto Butantan (IB), new specimens of this taxon were found, providing new data about geographic distribution, pholidosis, hemipenis, and some aspects of natural history. A specimen from the Museu de História Natural – Universidade Estadual de Campinas (ZUEC), and another from Museu Nacional – Universidade Federal do Rio de Janeiro (MNRJ), were also examined. The meristic and morphometric data of the examined specimens are reported in Table I. The method of ventral counting follows Dowling (1951) and the terminology for the hemipenis is based on Dowling and Savage (1960) and Myers and Campbell (1981). Criteria to determine the reproductive maturity follow Shine (1980). The measurements for snout–vent length (SVL), tail length (TL), and head length (HL) were taken with a ruler to the nearest millimeter. Individual eggs were measured (length and width) to the nearest 0.1 mm with a dial caliper. Regardless of the low number of specimens, especially males, a Mann-Whitney test was performed with the meristic characters to assign the presence or absence of sexual dimorphism.

The specimens presented herein represent five new localities for *L. atraventer* extending its geographical distribution (Fig. 1). All new records are from the state of São Paulo, southeastern Brazil. Five specimens (IB 28060, 46368, 61618–61620) are from the municipality of Tapiraí (23°57'S, 47°30'W), ca. 880 m elev. Two specimens (IB 54001, ZUEC 1308) are from the municipality of Cunha (23°04'S, 44°57'W), ca. 950 m elev. Another (IB 25295) is from the municipality of São Paulo (23°32'S, 46°38'W), ca. 760 m elev. The two remaining specimens (IB 40455, 65538) are from the municipality of São Roque (23°31'S, 47°08'W), ca. 770 m elev., and Parque Estadual Intervales, municipality of Ribeirão Grande (approximately 24°05'S, 48°21'W), ca. 700 m elev., respectively. These new localities, together with those reported by Dixon and Thomas (1985) and Passos and Fernandes (2001), are at or above 700 m elev.

The Mann-Whitney test did not reveal significant sexual dimorphism in the meristic characters examined (ventrals: $U = 8.5$; $p = 0.47$; $N = 11$; subcaudals: $U = 5.5$; $p = 0.46$; $N = 10$), but a larger series is needed to confirm this result. The following characters showed no variation in the specimens examined and are consistent with data presented by Dixon and Thomas (1985): dorsal scales rows: 19/19/17; supralabials 8, 4th and 5th contacting the orbit; preoculars 1; postoculars 2; temporals 2+1; loreals 1; genials 2 pairs. In the present paper, TL/total length ratios varied from 0.2 to 0.33 (mean = 0.25; s = 0.04; N = 8) for females and 0.2–0.3 (mean = 0.25; s = 0.07; N = 2) for males; reduction to 17 dorsal scales rows occurs through the fusion of scale rows 3+4 over ventrals 72–82 (mean = 77.27; s = 3.32; N = 11); ventral scales 142–149 (mean = 146.0; s = 2.56; N = 8) for females and 140–148 (mean = 144.33; s = 4.04; N = 3) for males; subcaudals 51–57 (mean= 52.75; s = 1.91; N = 8) for females and 52–56 (mean = 54.0; s = 2.83; N = 2) for males; infralabials 9–10, the first pair in

contact behind the symphisial, first to fifth contacting the first pair of genials, fifth and sixth contacting the second pair of genials; two pairs of genials; maxillary teeth 20–23 (mean = 21.36; s = 0.93; N = 11) (23–24 according to Dixon and Thomas [1985]), with the last two enlarged and separated from the remainder by a diastema.

Color in preservative: dorsum of the head, body and tail olive brown in specimens fixed during shedding, otherwise they have a bluish green aspect ("sea blue," according to Wilson [1941]); supralabials' lower edges grayish white ("Naples yellow," following Wilson [1941]); infralabials generally grayish white, sometimes with blotches, principally the posterior ones, of the same color as the dorsum; genials and gulars grayish white; anterior ventrals (approximately until 10^{th}) are usually grayish white and the ventrals become darker toward the posterior portion, being completely black in some specimens or having only the lateral edges grayish white; bands may form two ill-defined ventrolaterals lines as pointed out by Dixon and Thomas (1985); subcaudals grayish white, the anterior ones may have black blotches as observed by Dixon and Thomas (1985).

In life, the color of the dorsum is bright green ("emerald green" according to Wilson [1941]) and the venter varies from gray to black (see color photo and comments in Marques et al. 2001:53).

The hemipenis extends through 6–10 subcaudals (inverted organ; N = 3). Everted organ (N = 1) slightly bilobed; lobes smaller than the hemipenial body which has an inflated area in the basal portion; sulcus spermaticus divides approximately one third of the distance between the bottom of the hemipenial body and the point of bifurcation of the lobes; branches have centrifugal orientation and terminate in the median portion of the smooth apical disks located in the distal portion of the lobes; lobes have no calyculation or capitation; spinules covering the entire surface, except the inner surfaces of the lobes which are nude; each basolateral portion of the hemipenial body has large spines (ca. 15) arranged in several rows reaching the basal portion of the lobes [five large spines according to Dixon (1985)]; the asulcate side is mostly covered by spinules; the basolateral portion of the hemipenial body has large spines and the median portion of each lobe contains some medium sized spines; the retractor muscle originates at the level of 24^{th} to 25^{th} subcaudals (N = 3) (Fig. 2).

The habits of *Liophis atraventer* are poorly known. W. R. Heyer collected a specimen in a moist environment and it regurgitated eggs of an *Eleutherodactylus* sp. (Dixon and Thomas 1985). Marques et al. (2001) state that this species is diurnal and flattens the body dorsally or promotes a cloacal discharge as a defensive behavior.

We made a midventral incision in the preserved specimens to determine the presence of prey items in the gut, and vitellogenic follicles or eggs in the oviducts. The only prey item found was a frog of the *Physalaemus cuvieri* species group (IB 61618), swallowed head-first. The species of this group of *Physalaemus* are common in open areas, being found in pools sometimes associated with forest edges (J. P. Pombal Jr., pers. comm.). None of the nine females contained vitellogenic follicles > 5 mm, but three of them had oviductal eggs. One specimen collected in October (IB 25295, 633 mm SVL, 145 mm TL) contained 12 oviductal eggs (mean length = 16.9 mm, s = 2.7, range = 12–22 mm; mean width = 10.6 mm, s = 0.91, range = 9.3–12.4 mm). A second specimen collected in November (IB 40455, 690 mm SVL, 137 mm TL) contained eight oviductal eggs (mean length = 23.5 mm, s = 3.82,

range = 17.0–28.7 mm; mean width = 11.6 mm, s = 0.73, range = 10.5–12.5 mm). The third specimen collected in January is poorly preserved (IB 65538, 648 mm SVL, 150 mm TL) and had five oviductal eggs (mean length = 15.8 mm, s = 5.11, range = 10.0–22.2 mm; mean width = 7.5 mm, s = 0.9, range = 7.7–9.0 mm), and four atresic eggs. These data show that in the rainy season (October–January) *L. atraventer* is reproductively active, but our data are insufficient to suggest a continuous reproductive cycle. Vitt (1983) obtained reproductive data for a few species of *Liophis*, including *L. viridis*, a relative of *L. atraventer* (Dixon 1987). He argues that *L. viridis* has an extended reproductive season and possible multiple clutches. Marques (1996) suggested that continuous reproduction is possibly conservative in the tribe Xenodontini, therefore additional data are needed to ascertain the reproductive cycle of *L. atraventer*.

Acknowledgments.—We thank Ivan Sazima and Paulo R. Manzani for kindly loaning the specimen from Museu de História Natural – Universidade Estadual de Campinas, and José P. Pombal Jr. and Luciana B. Nascimento for the identification of and information about the prey item. We are grateful to Otávio A. V. Marques, José P. Pombal Jr., and Ronaldo Fernandes for their comments on the manuscript. James R. Dixon and Robert A. Thomas critically reviewed the manuscript and made many helpful suggestions. Financial support was provided by the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP), and Fundação Carlos Chagas Filho de Amparo à Pesquisa (FAPERJ).

Precision and Accuracy of Body-Size Measurements in a Constricting, Large-Bodied Snake (*Elaphe obsoleta*)

GABRIEL BLOUIN-DEMERS
Department of Biology, University of Ottawa, 150 Louis Pasteur Ottawa, Ontario, K1N 6N5 Canada
e-mail: gblouin@uottawa.ca

Size measurements are used in a wide variety of snake studies. Obtaining the snout-to-vent length (SVL) of snakes is necessary to study systematics (e.g., Burbrink 2001), sexual size dimorphism (e.g., Madsen 1983; Shine 1989), growth (e.g., Macartney et al. 1990; Forsman 1993), or demography (e.g., Plummer 1985). The body of a conscious snake, however, is elastic and can stretch and contract, yielding variable measurements of SVL. Also, a recent report that Galápagos marine iguanas (*Amblyrhynchus cristatus*) can dramatically decrease in body size when food availability is low (Wikelski and Thom 2000) raises the possibility that reptiles can shrink. Quantifying the precision and accuracy of SVL measurements is important (1) to improve measurement methods for snakes, (2) to partition the observed variance around parameters obtained from SVL measurements (e.g., growth estimates) into variance associated with measurement error and variance associated with individual differences, and (3) to determine whether reported instances of snakes shrinking (Blouin-Demers et al. 2002; Madsen and Shine 2001) can be attributed to measurement error or to previously unsuspected instances of shrinkage. I am unaware, however, of any study that has quantified the error associated with SVL measurements of snakes. My general goal in this paper was to quantify both the precision and accuracy of SVL measurements in black ratsnakes (*Elaphe obsoleta*), a large constricting colubrid.

My first objective was to quantify the precision of SVL measurements of conscious *Elaphe obsoleta* obtained by a method commonly used in field studies and consisting in running a flexible measuring tape along the venter of a snake held horizontally by an assistant (described by Fitch 1987). Measurement error on SVL arises from the behavior of the animal when being measured (struggling) and from limitations intrinsic to the measuring method. Thus, my second objective was to determine what proportion of measurement error was because of the struggling of the snake and what proportion was because of the measurement method itself. Because black ratsnakes are large constricting colubrids, I expected they would be difficult to measure and I predicted that the struggling of the snake should account for a greater proportion of measurement error than the limitations of the measuring method. My third objective was to quantify the accuracy of SVL measurements on conscious *Elaphe obsoleta* obtained by the method described

by Fitch (1987). Lastly, I wanted to determine whether precision and accuracy of SVL measurements varied with the size of the snake being measured. Large snakes, with their strong musculature, might struggle more vigorously and be more difficult to measure. Thus, I predicted that the SVL measures of larger snakes should be less precise and less accurate than those of smaller snakes.

Materials and Methods

In May 2000, 20 wild-caught *Elaphe obsoleta* from the Queen's University Biological Station (40 km N of Kingston, Ontario; 44°34'N, 76°19'W, 200 m elevation) were measured three ways and subsequently returned to the wild. Individuals were selected spanning the size range of *Elaphe obsoleta*, with the caveat that individuals had to be large enough (> 500 mm SVL) to be intubated for anesthesia (see below). First, to determine the precision of SVL measurements, each snake was measured 10 times using the method of Fitch (1987). The snake was held behind the head and behind the cloaca by an assistant. With the snake suspended horizontally, the assistant gently stretched it until the snake tired and extended to full length, at which point a 2-m flexible measuring tape was run along its venter (Fitch 1987). In all cases, the snake was measured twice and the mean of the two measurements was recorded. Using this method (hereafter "Conscious – Tape"), the 20 snakes were measured every day for 10 days, assuming that growth over those 10 days was negligible. Second, to quantify the error associated with the behavior of the snakes when being measured, the snakes were measured again, but first rendered flaccid by isoflurane anesthesia (Blouin-Demers et al. 2000). To avoid anesthetizing the snakes repeatedly, all 10 pairs of measurements were taken during a single dose of anesthesia, but the snakes were coiled on a table between each pair of measurements (hereafter "Anesthetized – Tape"). Third, to quantify the error associated with running the flexible measuring tape along the venter of the snakes, the anesthetized snakes were also measured 10 times by laying them on a table along a 2-m metal ruler. These last 10 pairs of measurements were also taken under anesthesia, but the snakes were loosely coiled on a table between pairs of measurements (hereafter "Anesthetized – Ruler"). Thus, the 30 measurements for each snake (10 measurements by 3 methods) each represent the mean of two measurements. Data collection was blind: the numbers on the measuring device were covered and the measuring device was simply marked, after which an assistant recorded the number.

The measure of precision was the coefficient of variation (CV; Zar 1999). Ideally, the SVL measurement obtained on a conscious snake would be identical to that obtained by measuring the snake when anesthetized (Fitch 1987). In the present study, however, the snakes were measured anesthetized using two different methods. Snakes stretched considerably when anesthetized and suspended in the air (see Results). Consequently, I considered that the "true" SVL of black ratsnakes was the mean of the 10 values obtained by the Anesthetized-Ruler method. Thus, the measure of accuracy for a particular method was the mean of the absolute values of the deviations of the SVL values from the "true" SVL, expressed as a percentage of the "true" SVL.

Repeated measure ANOVA (one within design) or paired t-test were used to analyze the precision and accuracy of each measurement method, and linear regression was used to determine whether precision or accuracy of measurements varied with SVL. The data were screened for violations of the assumptions of normality and homogeneity of variance using box plots and Shapiro-Wilk tests. All analyses were conducted on JMP Version 3.2 (Statistical Analysis Systems 1997) and SPSS Version 6.1 (Statistical Package for the Social Sciences 1995) on a Macintosh desktop computer. Means are reported ± 1 standard error.

Results

The three measurement methods differed in precision as measured by their CVs ($r^2 = 0.85$, repeated measures ANOVA $F_{(2,18)} = 103.42$, $P < 0.001$). Tukey post-hoc tests indicated that the three methods differed from one another. Measuring snakes by laying them along a ruler when they were anesthetized was the most precise method, followed by measuring them with a flexible tape when they were anesthetized, and then by measuring them with a flexible tape when they were conscious (Table 1). Nevertheless, measuring conscious snakes was surprisingly precise, with an average CV of 1.10 ± 0.10% and a maximum value of 2.16%. The calculation of CV involves the deviation of each measurement from the mean. The mean of the absolute values of those deviations gives a direct estimate of measurement error. The mean of the absolute values of the deviations from the mean SVL of the conscious snakes was 8.14 mm, or 0.82% of the mean SVL.

Assuming that measurement error is random and thus has a symmetrical distribution centered on the mean (my data do not suggest otherwise), the mean measurement error around a growth estimate based on two SVL measurements would be twice the measurement error of SVL (2 x 0.82% = 1.64%) half of the time. If errors are random, errors on two SVL measurements should be in opposite direction half of the time (and thus cumulative) and in the same direction the other half of the time (and thus noncumulative). During the active season, the average growth rate for a 1000-mm *Elaphe obsoleta* in Ontario is 0.4 mm/day (Blouin-Demers et al. 2002). Thus, when the errors are cumulative (i.e., 1.64% measurement error) it would take an average of 41 days of activity before growth of a 1000-mm individual becomes detectable using Fitch's (1987) measurement method.

The Anesthetized – Tape method was 44% more precise than

Table 1. Precision (CV), accuracy (absolute values of deviations of SVL), and mean SVL for 20 black ratsnakes measured by three methods. Tape refers to measuring snakes by running a measuring tape along their body while snakes are held horizontally. Ruler refers to measuring snakes by laying them on a table along a metal ruler.

	CV (%)			Deviations (%)			SVL (mm)	
Method	Mean	SE	Max	Mean	SE	Max	Mean	SE
Conscious – Tape	1.10	0.10	2.16	1.39	0.19	2.80	1046.7	62.1
Anesthetized – Tape	0.62	0.04	0.98	3.41	0.34	5.82	1075.1	66.6
Anesthetized – Ruler	0.16	0.02	0.40	—	—	—	1036.3	61.7

the Conscious – Tape method (Table 1), indicating that, on average, 44% of the imprecision when measuring conscious snakes was attributable to their activity (i.e., struggling). A further 42% increase in precision was achieved by the Anesthetized – Ruler method (Table 1). This result did not support my prediction that a greater proportion of measurement error would be attributed to the behavior of the snake when being measured, than to limitations of the measuring method.

The mean SVL of snakes obtained by the three methods differed from one another ($r^2 = 0.64$, repeated measures ANOVA $F_{(2,18)} = 32.65$, $P < 0.001$). Tukey post-hoc tests indicated that SVL values did not differ between Conscious – Tape and Anesthetized – Ruler methods, but the Anesthetized – Tape method yielded SVL values greater than the other two methods (Table 1). Based on the absolute values of the deviations from the "true" SVL, measuring snakes with the tape was less accurate when snakes were anesthetized than when they were conscious (paired $t_{(19)} = 5.77$, $P < 0.001$). These results were due to the anesthetized snakes stretching when they were measured with the tape.

Contrary to my prediction, precision of the Conscious – Tape method increased significantly with increasing SVL ($r^2 = 0.27$, $F_{(1,18)} = 6.57$, $P = 0.019$, Fig. 1). Precision was not significantly related to SVL ($F_{(1,18)} = 0.86$, $P = 0.366$) when snakes were anesthetized and measured with the tape (Fig. 1). Precision decreased significantly with increasing SVL ($r^2 = 0.22$, $F_{(1,18)} = 5.16$, $P = 0.036$) when snakes were anesthetized and measured with the ruler (Fig. 1). This last relationship, however, appears to be driven by one large snake with a high CV (Fig. 1). Excluding this data point from the analysis made the relationship non-significant ($F_{(1,17)} = 3.06$, $P = 0.099$). Contrary to my prediction that SVL measurements on larger snakes should be less accurate than those on smaller snakes, accuracy was not related to SVL for conscious snakes ($F_{(1,18)} = 1.04$, $P = 0.307$). Accuracy was, however, strongly related to SVL for anesthetized snakes ($r^2 = 0.79$, $F_{(1,18)} = 67.23$, $P < 0.001$). Larger snakes stretched proportionally more than smaller snakes when measured anesthetized and their SVL was thus overestimated to a greater extent (Fig. 2).

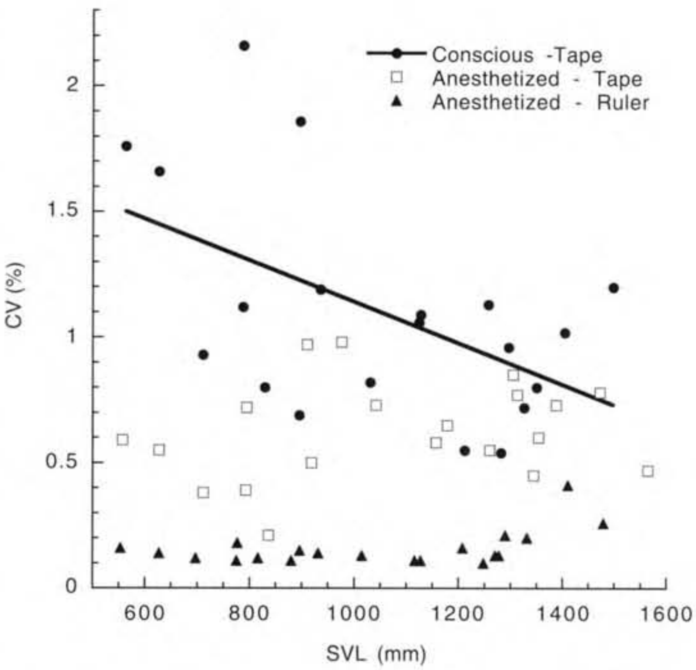

Fig. 1. Precision of SVL measurements (measured by the coefficient of variation expressed as a percentage) as a function of mean SVL for 20 black ratsnakes measured by three methods.

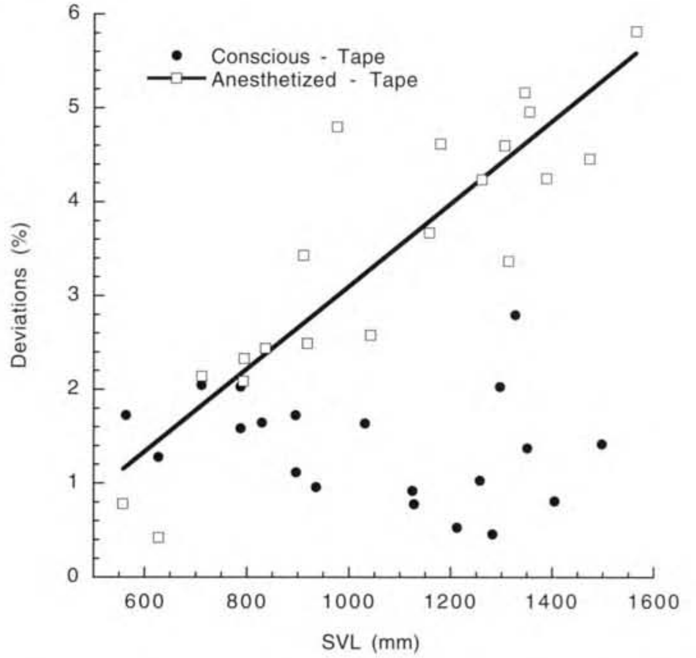

Fig. 2. Accuracy of SVL measurements (measured by the mean deviation of the SVL measurements from the "true" SVL expressed as a percentage) as a function of mean SVL for 20 black ratsnakes measured by two methods.

Discussion

I found that SVL measurements of conscious snakes were both precise and accurate (mean error ≈ 1%) and that the proportions of measurement error attributable to the behavior of the animal and to the measuring method itself were approximately equal. Precision of measurements increased with increasing SVL for conscious snakes. Accuracy of measurements on anesthetized snakes with tape, however, decreased with increasing SVL.

Contrary to my prediction, SVL measurements on a large-bodied constrictor such as *Elaphe obsoleta* were surprisingly precise. After an initial struggle when first grasped, ratsnakes in this study usually calmed down within 1–2 min. This resulted in (1) my ability to make precise measurements, and (2) the behavior of the snakes when measured accounting for approximately the same proportion of measurement error as limitations of the measurement method itself.

One unexpected result was that the precision of measurements increased with increasing SVL for conscious snakes measured with tape. Precision did not vary with SVL for anesthetized snakes measured with tape, suggesting that the behavior of the snakes when being measured causes the difference in precision between large and small snakes. Thus, it appears that larger snakes, which tend to be more placid, are easier to measure than are smaller snakes because larger snakes provide more precise measures. Accuracy did not vary with SVL for conscious snakes. However, measuring anesthetized snakes with tape tended to slightly overestimate their

SVL, and this problem was more severe for larger snakes.

Because SVL measurements in conscious snakes are both precise and accurate, it should be possible to detect instances of shrinkage (Madsen and Shine 2001; Wikelski and Thom 2000) if they do occur in snakes. Based on the small magnitude and low frequency of negative growth estimates in this population (Blouin-Demers et al. 2002), it seems unlikely that shrinkage occurs. Individual cases of apparent shrinkage were thus likely due to measurement error.

In summary, my data suggest that the best way to measure the SVL of snakes is by anesthetizing them and laying them next to a ruler. If this method is not practical, measuring them conscious with a flexible tape (Fitch 1987) is a reasonable alternative.

Acknowledgments.—The protocols for this experiment were approved by the Carleton University Animal Care Committee (Protocol B97-1). I am grateful to H. McCracken and C. Verreault for their able help with data collection. P. Weatherhead, R. Espinoza, and two anonymous reviewers provided comments that improved this manuscript. Logistical support for my work was provided by the Queen's University Biological Station. This research was supported by NSERC postgraduate scholarships to the author and an NSERC research grant to P. Weatherhead.

Multiple Recaptures of a Hybrid Hawksbill-Loggerhead Turtle in the Ten Thousand Islands, Southwest Florida

The Miami Laboratory of the National Marine Fisheries Service (NMFS) conducted a study to determine the distribution and abundance of immature sea turtles in the nearshore waters of southwest Florida. Standard mark-recapture techniques were used as described in Eckert et al. (1999), and tissue samples were taken from green, loggerhead, and hawksbill turtles for genetic analysis.

The NMFS turtle survey documented the presence of immature Kemp's ridley (*Lepidochelys kempi*), loggerhead (*Caretta caretta*), and green (*Chelonia mydas*) sea turtles in the coastal waters of southwest Florida, in order of decreasing abundance. One turtle, originally identified as an immature hawksbill (*Eretmochelys imbricata*), was captured on 15 October 1998. Hawksbill turtles are considered a tropical species more commonly found in coral reef habitats (Meylan 1992; Witzell 1983), and it seemed unusual that this turtle was caught in the turbid waters of the Ten Thousand Islands in southwest Florida. The turtle's shape, scale pattern, and color were not readily distinguishable from a "normal" hawksbill. However, nuclear DNA analysis demonstrated that this animal was, in fact, a hawksbill-loggerhead hybrid, a rare phenomenon previously documented (Bowen and Karl 1997; Karl et al. 1995). Researchers from the University of South Florida in Tampa, Florida analyzed tissue samples from the turtle. Maternally inherited mtDNA was used to resolve maternal parent. The control region sequence from the mitochondrial DNA matched *Caretta caretta* haplotype A, indicating that the maternal parent was a loggerhead. Restriction digests of three nuclear DNA loci (CM-12A, CM-28, CM-14A) were performed using restriction enzymes *Rsa I*, *Bst NI*, and *Dra I*, respectively. Together, these three digests indicate the turtle is a post-first generation (F1) hy-

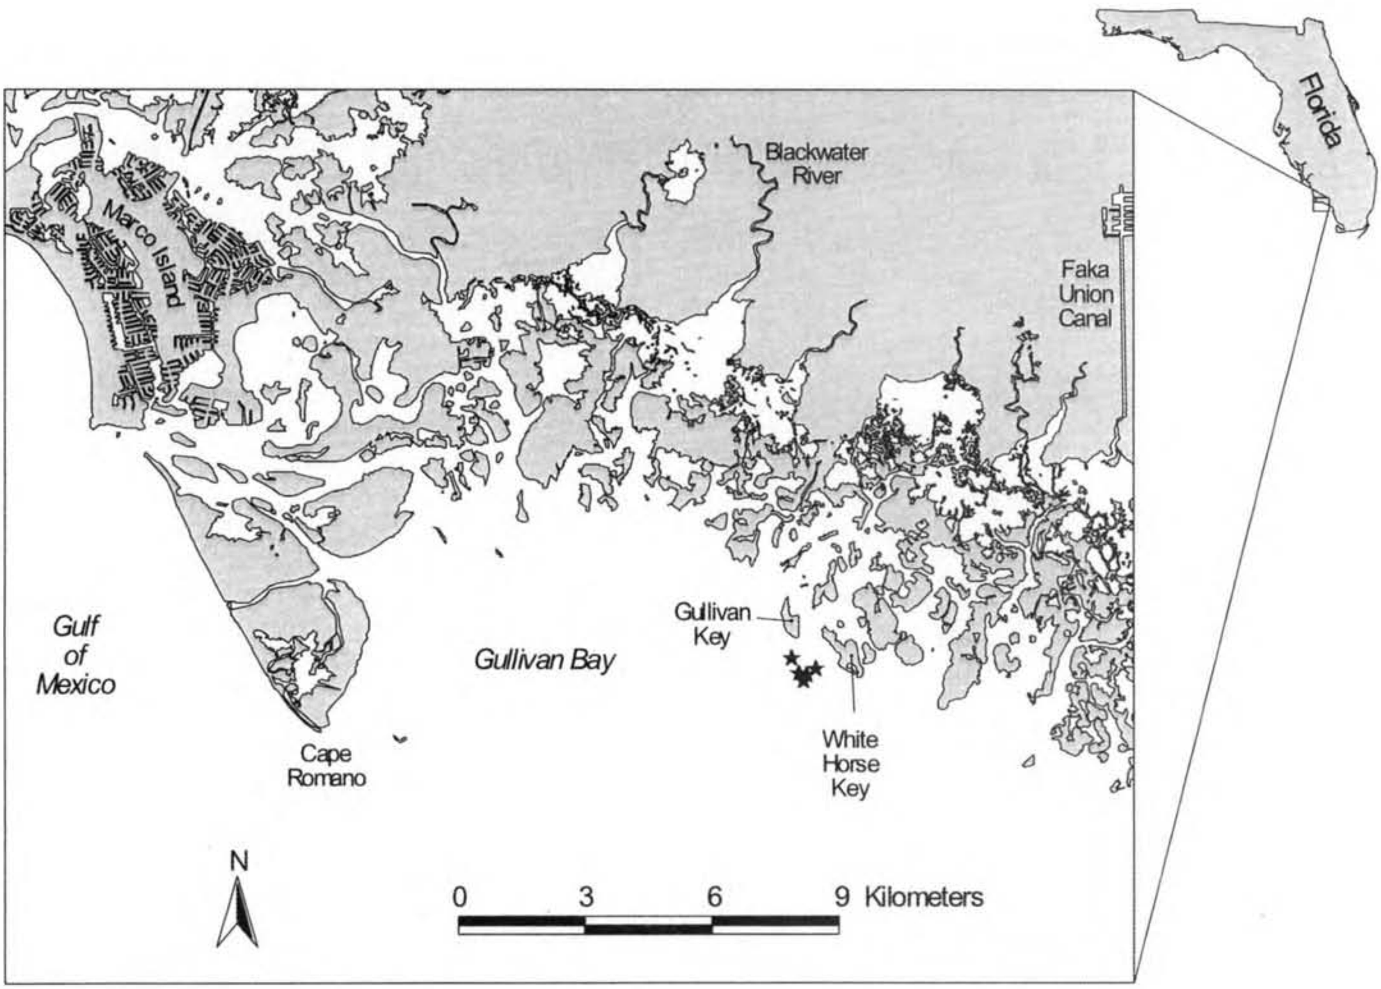

FIG. 1. Ten Thousand Island study area with multiple recapture sites of an immature hybrid hawksbill-loggerhead turtle.

brid between *Caretta caretta* and *Eretmochelys imbricata*. Bowen et al. (1993) provided a molecular phylogeny of sea turtles and concluded that the hawksbill-loggerhead split was nearly 20 million years ago, and the hawksbill-loggerhead hybrid is unique because there are few hybrids between vertebrate species separated by more than five million years.

Intensive surveys in Gullivan Bay have documented only this one putative hawksbill turtle, the majority of turtle sightings being immature Kemp's ridleys. The turtle was recaptured four times over 711 days (Table 1), and all recaptures were within 600 m of the initial capture location. This suggests that the turtle had established a home range within a non-typical hawksbill habitat between Gullivan and White Horse Keys (Fig. 1). The home range of the five recaptures encompasses 14.11 ha, consistent with the home ranges of immature hawksbills on tropical coral reefs (Van Dam and Diez 1998). The small home range suggests that this turtle had located an isolated hard-bottom community with sufficient food to keep it in the vicinity for close to two years. These hard-bottom community organisms typically consist of various sponges, bryozoans, and tunicates.

The warm estuarine environment of coastal southwest Florida promotes the growth of encrusting organisms. This turtle was noted as having "numerous barnacles on carapace, plastron, head and axial regions of flippers" (Fig. 2), indicating that it had resided within these waters for some time prior to first capture. An oyster and additional barnacles were noted on the subsequent captures. On the last capture, an astonishing mass of barnacles, tunicates, and bryozoans was noted on the carapace, in addition to a myriad of attendant crustaceans (Fig. 2). Epibiota communities like these are more commonly found on loggerheads (Dodd 1988) than hawksbills (Witzell 1983). In spite of this growth, the turtle appeared to be robust and healthy. The turtle grew from 52.2 cm to 64.6 cm during 711 days (6.5 cm/year) and gained 5 kg (2.6 kg/year). A substantial head wound above the left eye was noted at the 16 November 1999 capture. The cause of the wound is unknown, but it was healed by the 4 September 2000 capture, illustrating the powerful recuperative capabilities of this individual.

Reports of hawksbill turtles from non-coral reef habitats are uncommon. Hawksbills have been documented from a mangrove habitat in El Salvador (Hasbun et al. 1998) and the turbid northern Gulf of Mexico waters (Rester and Condrey 1996). Interestingly, Carr (1952) reported hawksbills from mangrove-bordered bays, including three turtles that had eaten large quantities of red mangrove fruit, leaves, and bark. Perhaps these turtles were also hawksbill-loggerhead hybrids, as the photo of the specimen from the northern Gulf of Mexico suggests (Rester and Condrey 1996). The apparent residency of a hybrid hawksbill-loggerhead turtle in the Ten Thousand Islands is considered very unusual, primarily because this turtle had the gross appearance of a hawksbill, but it also collected epibionts on the carapace similar to loggerheads

and inhabited a habitat more typical of a loggerhead than hawksbill.

Acknowledgments.—We thank Steven A. Karl and Tonia Schwartz for providing genetic analysis and interpretation expertise, and Anne Meylan for suggesting that this turtle might be a hybrid. We also thank Brian W. Bowen for providing comments on this manuscript.

We observed the mating behavior of *Carlia jarnoldae* during austral summer (January–March 1999) in Townsville, Queensland, Australia (19°19'S, 146°45'E). *Carlia jarnoldae* are relatively small (mean snout–vent length 40 mm), terrestrial, diurnal lizards (Cogger 2000). Adults are sexually dimorphic: males are heavier (2.4 g vs. 1.9 g), but not longer (adult males average 44 mm SVL, 68 mm tail length; females average 43 mm SVL, 64 mm tail length), and males are more colorful than are females (Cogger 2000). Breeding males have an orange-brown dorsum with 4–6 narrow black stripes, a black dorsolateral field scattered with small blue spots, and a reddish-orange lateral stripe. The labial scales and throat of males are pale greenish-blue. Females are brown above with scattered black and white flecks tending to form longitudinal lines, and a bright white lateral stripe bordered above and below by black stripes.

We observed 16 social interactions in which a single adult female was placed into a 1000 L (200 x 100 x 50 cm) oval, semi-natural outdoor enclosure with an adult male. We also made observations of ten individuals in nature. Observations were conducted from behind a freestanding hessian blind. Four copulations were observed in the experimental enclosures (one of these took place under a shelter and could not be observed) and two in the wild.

Courtship.—Males tongue-flicked females during courtship. This behavior occurs in other lizards and suggests an important role of chemical cues in sexual identification and stimulation (Carpenter and Ferguson 1977; Mason 1992; Perrill 1980). Courtship was observed in seven of the social interactions conducted in the enclosures, but resulted only once in copulation.

A courting male would often pursue or approach a female (also while moving with a slow, jerky motion, and tongue flicking), and if the female showed no interest, the male would run to the top of one of the shelters, usually in the sun, and display their lateral coloration by laterally presenting and dorsoventrally compressing their bodies, tilting to the side towards the female. Male throat coloration was displayed by tilting their heads to expose their gular coloration in the direction of the female, before again approaching the female. Copulations not preceded by courtship behavior were initiated shortly after the female was encountered. In cases in which the females did not appear receptive, they would flee from males and hide under shelters or leaves. The male would then search for the female (either simply approaching the female, approaching the female in a slow, jerky motion, or approaching the female while tongue flicking).

Copulation.—Once he located the female, the male initiated copulation. The female often struggled at the onset of these copulations, but became motionless after ~1 min. In the single case that copulation followed courtship, the female allowed the male to approach, initiate a flank bite, and copulate without struggling. When courtship displays did not result in copulation, it was usually because of rejection by the female (i.e., she would flee to a shelter and hide). The copulatory position was similar in all cases, and resembled that described for other skinks (*Carlia* [*Leiolopisma*] *rhomboidalis*, Wilhoft 1963a; *Carlia rostralis*, Whittier 1994; *Eulamprus* [*Sphenomorphus*] *kosciuskoi*, Done and Heatwole 1977; *Eumeces fasciatus*, Fitch 1954; *Eumeces obsoletus*, Evans 1953). To assume a position for copulation, males initiated a flank bite and placed the hind leg nearest the female over the base of her tail, while bringing the base of his tail up and under hers so that their cloacae were opposed (as illustrated in Whittier 1994). The male would thrust his tail and pelvic region as a single hemipenis was inserted into the female and copulation commenced. Pelvic thrusting continued for most of the time the cloacae were in opposition, but ceased before the flank was released. Copulations lasted an average of 3.92 min ($\pm$ 0.18 SE), which is considerably shorter than the 90 min reported for the skink *Eumeces egregius* (Mount 1963), but similar to the 3–5 min reported for the more closely related skink, *Carlia rostralis* (Whittier 1994). The number of thrusts was recorded for only two mating events ($N = 22$ for the one observed in the enclosures and $N = 36$ for the one in the field), and occurred at a rate of 5–6/s. This rate is faster than that observed in *C. rostralis*, which spasmed at a rate of 1 thrust/s, but this increased to 1–4/s in the final 30 s of intromission (Whittier 1994). Mating ceased when the male released his grasp on the female. The male then dragged his cloaca along the substratum with his hemipenis everted. This behavior may function to clean the hemipenis of seminal fluid, or possibly to leave chemical messages for other individuals (Beck 1990). Hemipenes remained everted for up to 2 min after copulation.

Female Receptivity.—Our data suggest that female *C. jarnoldae* are receptive to males after laying eggs, but not while they are gravid. During midsummer three of the four females that were observed copulating in the enclosure had deposited their eggs 1–7 days before mating. These females were exposed to different males prior to laying, but refused courtship advances from these males and did not allow copulation to occur. In all cases of rejection, females were observed to perform a characteristic behavior: females positioned themselves in front of the male, facing away, but with their tails directed towards him. In this position, females waved their tails in a horizontal plane, held posterior to the body, so that their tails waved near his face. If the male moved, the female would often move in front of him and again wave her tail in his face. Usually this caused the male to cease courtship, and resume foraging or basking behaviors. Although this behavior may simply signal that the female is not receptive, it may also provide pheromonal cues (Mason 1992; Shine et al. 2000) because the males often tongue flick the female's cloaca following this display. Regardless of their purpose, these behaviors warrant further study.

Clutch Size.—Females produced one ($N = 4$) or two ($N = 5$) small, white eggs under the shelters provided in the enclosures. *Carlia* spp. typically produce two eggs (Cogger 2000; Zug et al. 1982), although it is possible that in cases where only one egg was found, the second was deposited at a later stage (Zug et al. 1982). Only one egg was hatched in the laboratory, 10 d after being found in the enclosure (we checked under the shelters for eggs approximately every 3 d). The hatchling was 19 mm SVL, with a 29 mm tail, and weighed 0.2 g. In the Townsville region, *Carlia jarnoldae* reproduce annually, with oviposition occurring in the late spring or summer (November to June), coinciding with the wet season (James and Shine 1985; Wilhoft 1963b; Zug et al. 1982; TL and LS, unpubl. observations).

Acknowledgments.—This manuscript was greatly improved by the comments of F. Seebacher, R. Swain, and one anonymous reviewer. We also thank N. Peterson for field observations. The research presented here adhered to the Guidelines for the Use of Animals in Research, the legal requirements of Australia, and the guidelines for James Cook University, Townsville. Ethics approval was obtained from James Cook University Ethics Committee: certificate number A515. Animal collection was covered by a Scientific Purposes Permit number NO/001257/96/SAA.

Defensive Strategies of Texas Horned Lizards (*Phrynosoma cornutum*) Against Red Imported Fire Ants

STEPHEN L. WEBB
and
SCOTT E. HENKE
Caesar Kleberg Wildlife Research Institute, MSC 218
Texas A&M University-Kingsville
Kingsville, Texas 78363-8202, USA
e-mail (SEH): scott.henke@tamuk.edu

The Texas horned lizard (*Phrynosoma cornutum*), a state-listed threatened species, historically occurred throughout most of Texas, but its distribution and abundance has declined dramatically (Henke 2003). Possible reasons for the decline include widespread use of broadcast insecticides, excessive commercial collection, loss of habitat from urbanization and/or agriculture, and the invasion of the red imported fire ant (*Solenopsis invicta*; Donaldson et al. 1994). Potentially, fire ants can negatively impact Texas horned lizards indirectly through competition with harvester ants (*Pogonomrymex* sp.), the main prey item of Texas horned lizards, or directly by their venomous sting (Allen 1993). Similar decline of coastal horned lizards (*Phrynosoma coronatum*) in southern California has been attributed to the invasion of Argentine ants (*Linepithema humile*; Suarez and Case 2002).

Nonaggressive defensive strategies of Texas horned lizards include reliance on cryptic coloration, burrowing into the soil to avoid detection, retreating from predators using a sprint-and-freeze tactic, inflating their body with air, and various defensive stances (Peslak 1985; Pianka and Parker 1975; Reeve 1952; Sherbrooke 1981). Aggressive strategies include hissing and lunging at the predator, biting, jabbing with the occipital horns, or ejecting blood from the conjunctival sac located near the eye (Lambert and Ferguson 1985; Middendorf and Sherbrooke 1992; Sherbrooke and Middendorf 2001). Because Texas horned lizards have not evolved with red imported fire ants, novel defensive strategies may be used to cope to this exotic invertebrate.

We describe two defensive strategies exhibited by Texas horned lizards against red imported fire ants. The two strategies appear to be dependent on the number of ants involved in the attack. Our observations of encounters with Texas horned lizards and fire ants occurred in central and southern Texas (Atascosa, Brooks, Coryell, Frio, Kleberg, and LaSalle counties) from 16 June 2000–20 September 2001. Horned lizards were encountered while observers were conducting reptile and ant surveys. Observers did not disturb horned lizards or ant mounds and maintained ~1.5 m distance from lizards, until lizards buried themselves. At this point, observers would closely inspect the location where lizards were buried. The first strategy, referred to as the consumption strategy (N = 5), occurred when ≤ 12 fire ants were present (Table 1). When adopting this strategy, horned lizards remained very still with their eyes shut, occasionally twitching or jerking their heads as the ants ran across their eyelids. When the ants ran onto or around a lizard's mouth, the lizard would consume them. This continued until the majority of the ants were consumed or retreated from the lizard. The second defensive strategy, referred to as the flee-and-bury strategy (N = 6), occurred when > 20 fire ants were involved in the attack (Table 1). Twenty to > 50 fire ants swarmed onto the body of a horned lizard when the lizard disturbed a fire ant mound. Horned lizards that encountered > 20 fire ants sprinted 2.5–7 m from attack sites and quickly buried themselves, tail first, into the soil. Soils ranged from sandy, sandy-loam, gravelly loam, to clay loam soil, dependent upon location. Horned lizards wagged their tails and shifted their bodies from side to side until they were completely buried below the surface. Fire ants would then appear, within 15 s, on the surface above where the lizard was buried. Horned lizards re-emerged between 5–15 min afterwards.

Both strategies thwarted the attacks of fire ants on Texas horned lizards. We consider the consumption strategy to be a defensive strategy rather than a primary means of obtaining food. Texas horned lizards are considered dietary specialists (Whitford and Bryant 1979), with 69% of their diet consisting of harvester ants (Pianka and Parker 1975). Texas horned lizards appear resistant to the venom of harvester ants (Schmidt et al. 1989). Although Texas horned lizards consume other species of insects (e.g., crickets, grasshoppers, beetles, centipedes, bees, and caterpillars; Milstead and Tinkle 1969; Munger 1984), they do not actively prey on fire ants (S. E. Henke, unpubl. data). Argentine ants were never de-

TABLE 1. Defensive strategies of Texas horned lizards when attacked by red imported fire ants in Texas. Attacking ants were either consumed or returned to the soil surface after the horned lizard buried itself (see outcome column).

Sex	Snout–vent length (mm)	Number of ants in attack	Strategy	Outcome
Female	65	7	Consumption	5 consumed
Male	72	9–10	Consumption	5 consumed
Male	63	6	Consumption	4 consumed
Male	68	6–8	Consumption	4 consumed
Female	75	12	Consumption	9 consumed
Male	62	25–30	Flee and bury	20+ to surface
Female	78	20–25	Flee and bury	15 to surface
Female	69	25–30	Flee and bury	25 to surface
Male	47	20–25	Flee and bury	18 to surface
Female	65	25–30	Flee and bury	20+ to surface
Male	62	50+	Flee and bury	35+ to surface

tected in coastal horned lizard scat (Suarez et al. 2000), indicating that the lack of selection for invasive ant species as prey is not exclusive to Texas horned lizards. The flee-and-bury strategy appears to have a dual purpose. First, it places distance between the lizard and the fire ant mound. Second, the soil may be abrasive causing fire ants to release their grasp as the lizard buries as suggested by the appearance of fire ants on the surface within 15 s of a lizard burying itself.

We acknowledge that our observations of defensive strategies may not be exclusive to red imported fire ants. Native fire ants (*Solenopsis geminata*) also occur in southern Texas. However, because colonies of red imported fire ants are common, achieve high densities, and are more aggressive than are native fire ants (Porter and Savignano 1990; Porter et al. 1991), red imported fire ants may be more likely to elicit a defensive response from Texas horned lizards.

Acknowledgments.—We thank M. C. Oviedo for assistance with observations, and R. E. Espinoza, A. V. Suarez, and W. C. Sherbrooke for review of an earlier draft of this manuscript. Funding was provided by The Nature Conservancy of Texas. This is contribution number 03-104 of the Caesar Kleberg Wildlife Research Institute.

Descriptive studies have been conducted on squamate reproduction in many different environments (Benabib 1994; Guillette 1981, 1982; Lemos-Espinal et al. 1999; Ramírez-Bautista and Vitt 1997, 1998). These studies have provided data to enable formulating and testing hypotheses on life history evolution. Seminal in this development were the studies of Tinkle (1969) and his colleagues (Tinkle et al. 1970), who showed that lizard species that invest more energy in each reproductive event tend to be early-maturing, short-lived, and highly fecund. In contrast, species that invest less energy in each reproductive event distribute it over more time, and thus, tend to be late-maturing, long-lived, and have fewer clutches. More recently, studies have shown that a portion of life history variation among species is historical (Dunham and Miles 1985; Dunham et al. 1988). That is, related species tend to be more similar in life history characteristics than unrelated ones. For example, SVL at sexual maturity, clutch and egg size, and clutch frequency in *Sceloporus* are more similar within species groups (*scalaris* and *spinosus*) than between them (Valdéz-González and Ramírez-Bautista 2002). Such reproductive characteristics have only been sparsely addressed among lizards from tropical arid habitats. Thus, conclusions regarding patterns of life history characteristics among lizards from such habitats will remain vulnerable to change until considerably more data become available.

To help remedy this deficiency, I present data on selected reproductive characteristics (SVL at sexual maturity, clutch size, and clutch frequency) for a tropical arid lizard assemblage from Zapotitlán Salinas, Puebla, México. Zapotitlán Salinas (18°07'18"N; 97°39'06"W) is located at an elevation of 1420 m; the climate is dry and temperate with most precipitation occurring during the summer months (June–September). Mean annual temperature is 21°C (range 17–24°C) and mean annual precipitation is 450 mm (García 1981). Dominant vegetation consists of thorn

TABLE 1. Size and reproductive data for a lizard assemblage from Zapotitlán Salinas, Puebla, México.

Species	N	Snout–vent length (mm)				Collection	SVL at	Clutch Size				
		Mean	SE	Range		Months	Maturity	N	Mean	SE	Range	
				Min	Max						Min	Max
Anolis quercorum	4	40.0	1.2	38.0	43.0	Jul–Sep	38.0	4	1.0	—	1	1

forest, xerophytic brushland, deciduous tropical forest, and columnar cacti (Dávila et al. 1993; Rzedowski 1978).

The local lizard assemblage consists of 11 species (*Anolis quercorum*, *Cnemidophorus parvisocius*, *C. sacki*, *Ctenosaura pectinata*, *Phrynosoma taurus*, *Phyllodactylus bordai*, *Sceloporus gadoviae*, *S. horridus*, *S. jalapae*, *Urosaurus bicarinatus*, and *Xenosaurus rectocollaris*: Mata-Silva 2000). Except for two viviparous species (*P. taurus*: Zamudio and Parra-Olea 2000; *Xenosaurus rectocollaris*: Lemos-Espinal et al. 1996), most species in this assemblage (82%) are oviparous. I present data on 55 females belonging to 7 of the oviparous members of this assemblage (Table 1). All individuals were collected during April–December, with most taken in July–September, the mid-wet season. Lizards were humanely killed, measured snout–vent length (SVL) to the nearest 1.0 mm, fixed with 10% formalin, and subjected to gonadal examination.

During gonadal examination, I counted the number of vitellogenic follicles and/or oviductal eggs: I recorded the length and width of left and right vitellogenic follicles or freshly ovulated eggs to the nearest 0.1 mm; and weighed the eggs to the nearest 0.01 g.

Length and width of the gonads were used to obtain follicular and egg volume (V) using the formula for volume of an ellipsoid (Selby 1965):

$$V = 4/3\ \pi a^2 b$$

where a is half the shortest diameter and b is half the longest diameter. The smallest female (as SVL) with either the largest vitellogenic follicles or oviductal eggs was used to estimate minimum size at maturity. Means are presented ± 1 SE. Statistical analyses were performed with the Macintosh version of Statview 4.5 (Abacus Concepts 1992).

Sample sizes varied from 2 to 21 individuals among the 7 species (Table 1). Only three species (*C. parvisocius*, *S. gadoviae*,

TABLE 2. Clutch characteristics for lizards from Zapotitlán Salinas, Puebla, México. Minimum and maximum SVL and corresponding clutch data are given for each species, except for *A. quercorum*, which clutch size is fixed. Clutch size represents the oviductal eggs, and relative clutch mass (RCM) is based in all females with oviductal eggs for each species.

Species	SVL	Clutch			
		Size	Volume (mm^3)	Mass (g)	RCM
Cnemidophorus parvisocius	54.0	1	529	0.43	0.190
	62.0	2	359	0.78	
Cnemidophorus sacki	92.5	5	189	1.80	0.147
	124.7	6	228	1.74	
Sceloporus gadoviae	49.0	4	170	0.82	0.219
	67.0	4	502	1.75	
Sceloporus horridus	62.0	6	361	3.10	0.335
	92.0	14	615	9.60	
Sceloporus jalapae	43.0	4	120	0.52	0.329
	50.0	7	199	1.05	
Urosaurus bicarinatus	42.0	3	119	0.57	0.238
	54.0	8	265	1.35	
Anolis quercorum	43.0	1	255	0.20	0.097
	38.0	1	253	0.18	
	41.0	1	170	0.15	
	38.0	1	194	0.17	

and *S. jalapae*) had sample sizes ≥ 10; the remaining 4 species had ≤ 4 individuals each. Three species (*A. quercorum*, *S. jalapae*, and *U. bicarinatus*) could be characterized as small (≤ 50 mm SVL), two (*S. gadoviae* and *C. parvisocius*) as medium-sized (> 50 mm and ≤ 60 mm SVL); and two (*C. sacki* and *S. horridus*) as large (> 60 mm SVL).

Size at Sexual Maturity.—The three small species became sexually mature at 38.0 to 43.0 mm SVL; the two medium-sized species were mature at 49.0 mm and 54.0 mm, respectively; and the two large species matured at 62.0 mm and 92.5 mm, respectively (Table 1). Across the 7 species, the estimate of the size at sexual maturity was significantly positively correlated with both estimates of mean and maximum body size (Spearman Rank correlation: size at sexual maturity: $r = 0.929$, $p = 0.0229$; maximum size: $r = 0.964$, $p = 0.0182$).

Clutch Size.—Clutch size among the 7 species varied from 1 to 14 (Table 1). The sceloporine lizards (*Sceloporus* and *Urosaurus*) had higher mean clutch sizes than all non-sceloporine species except for *C. sacki*. Clutch size for *S. gadoviae* reported here is larger than that found for the same species at Río Balsas (mean = 3.6 eggs [1–5]; Lemos-Espinal et al. 1999) and Zapotitlán Salinas (mean = 3.9 eggs [2–5]; Correa-Sánchez et al. 1999). Clutch size for *U. bicarinatus* reported here is similar than that for *U. bicarinatus* at Morelos (mean = 7.7 eggs [3–8]; Ramírez-Bautista et al. 1995), but larger than that found in Chamela (mean = 5.4 eggs [4–8]; Ramírez-Bautista and Vitt 1998) and Michoacán (mean = 5.8 eggs [3–7]; Ramírez-Bautista et al. 1995). The differences of the clutch size among populations of *S. gadoviae* and *U. bicarinatus* reflect either phenotypic response to differing environments or local adaptation (Ramírez-Bautista and Vitt 1998). This analysis assumes that clutch sizes obtained from dissection reflects clutch sizes at oviposition; resorption of eggs may result in differences. Considering the small sample sizes, additional studies will be necessary to determine causes of differences. Some evidence suggests that multiple clutches are deposited within each season. *Anolis quercorum* females (N = 4) had one egg in one oviduct (right or left) and one vitellogenic follicle in the ovary simultaneously, and also had 8 and 16 nonvitellogenic follicles. Similarly, *C. parvisocius* only had one egg in each oviduct and one vitellogenic follicle in each ovary simultaneously, but one female had only one egg in the left oviduct and one vitellogenic follicle in the right ovary. Multiple clutching with extended oviposition for *A. quercorum* and *C. parvisocius* is similar to that reported among other anoline and teiid lizards (Ramírez-Bautista and Vitt 1997; Ramírez-Bautista et al. 2002; Vitt and Breitenbach 1993). Data are too sparse to confidently establish the seasonal pattern of reproduction (reproductive interval and clutch frequency) among sceloporine lizards studied here. However, data agree with the wet season reproduction interval previously reported for *S. gadoviae* (Lemos-Espinal et al. 1999), *S. horridus* (Valdéz-González and Ramírez-Bautista 2002), and *U. bicarinatus* (Ramírez-Bautista et al. 1995; Ramírez-Bautista and Vitt 1998), and wet season reproduction may be a general pattern for most lizard species in this assemblage.

Clutch volume.—Considerable variation in clutch volume and egg mass was found (Table 2). Females of *S. jalapae* had the smallest clutch volume; *A. quercorum*, *U. bicarinatus*, and *C. sacki* had an intermediate clutch volume, and *S. gadoviae*, *C. parvisocius*, and *S. horridus* had the largest clutch volume (Table 2). Clutch mass also varied among species, smallest clutch mass was found in *A. quercorum* and the largest in *S. gadoviae* and *S. horridus* (Table 2). Relative clutch mass (RCM; Vitt and Congdon 1978) among six species varied from 0.097 (anole lizard) to 0.335 (sceloporine lizard; Table 2). As in other studies, RCM reflects the influence of foraging mode on the evolution of morphology within whiptail and *Anolis* lizards (lower RCM) and sceloporine lizards (higher RCM).

Additional data are needed to make conclusions about the apparent variation in clutch size and other reproductive characteristics in this lizard assemblage. Basic data on clutch frequency and reproductive seasonality-should provide more insight into the ecological and phylogenetic basis of this variation.

Acknowledgments.—This study was part of a general project of Unidad de Biología, Tecnología y Prototipos (UBIPRO) in Zapotitlán Salinas. I thank Luis Oliver-López, Karla Abbadié-Bisogno, and Vicente Mata-Silva for field help, Laurie Vitt and Jonathon Marshall for reading and improving the manuscript, and Marc P. Hayes for his tremendous help to improve the manuscript and editorial suggestions. DGAPA (Dirección General de Apoyo al Personal Académico) grant IN 208398 of the Laboratory of Ecology and Dra. P. Dávila project IN 203598 supported this project.

Atelopus cruciger is a toad endemic to the lowland rainforest and cloud forest of the Cordillera de la Costa (Lötters 1996), and is the only species of the genus from Venezuela found outside the Andes. As for other *Atelopus* species, *A. cruciger* is diurnal, terrestrial, and breeds along swiftly flowing streams (Lötters 1996; Sexton 1958). Its historical abundance in many localities is evident in museum collections and in the literature (Cocroft et al. 1990; Mebs 1980; Mondolfi 1976; Sexton 1958). With no obvious explanation, the abundance of this species drastically decreased in the mid 1970's and early 1980's (La Marca and Lötters 1997; C. Señaris and J. Manzanilla, pers. comm.), and the last two specimens were collected in 1986 (Fig. 1).

As in many other amphibian species, losses do not seem to be caused by habitat degradation (Laurance et al. 1996; Lips 1999; Pounds and Crump 1994). Recent research has implicated *Batrachochytrium dendrobatidis,* a chytrid fungus, in declines of amphibian populations in Australia, USA, Costa Rica, Panama, Ecuador, Spain, and New Zealand (Berger et al. 1998; Bosch et al. 2001; Bradley et al. 2002; Ron and Merino 2000; Waldman et al. 2001). *Batrachochytrium* is a highly virulent pathogen for many amphibians, and in experimental situations mortality can be 100% (Speare 2001).

To explore the possible chytrid fungus infection of *Atelopus cruciger,* we obtained a complete record of the localities at which *A. cruciger* was collected (Appendix I). Then, we examined histo-

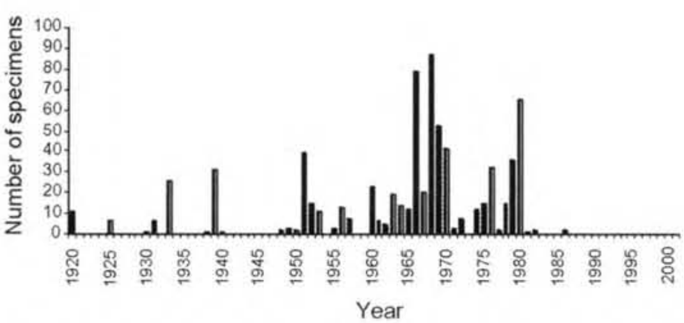

FIG. 1. Number of specimens of *Atelopus cruciger* in 12 herpetological collections (see acknowledgments) from 1920–2001. Note the absence of records after 1986.

logical preparations of specimens collected from 1920–1986 at localities across the historical distribution of the species (Fig. 2; Appendix I).

We removed strips of skin from the ventral surface of Toe IV from 59 specimens preserved in 70% ethanol. Tissue samples were tested for fungal infection following the procedures described in Berger et al. (1999). To remove bias, the histological examination of toad skin was carried out using a blind procedure with the scientist (DM) conducting the examination in the absence of any specimen data.

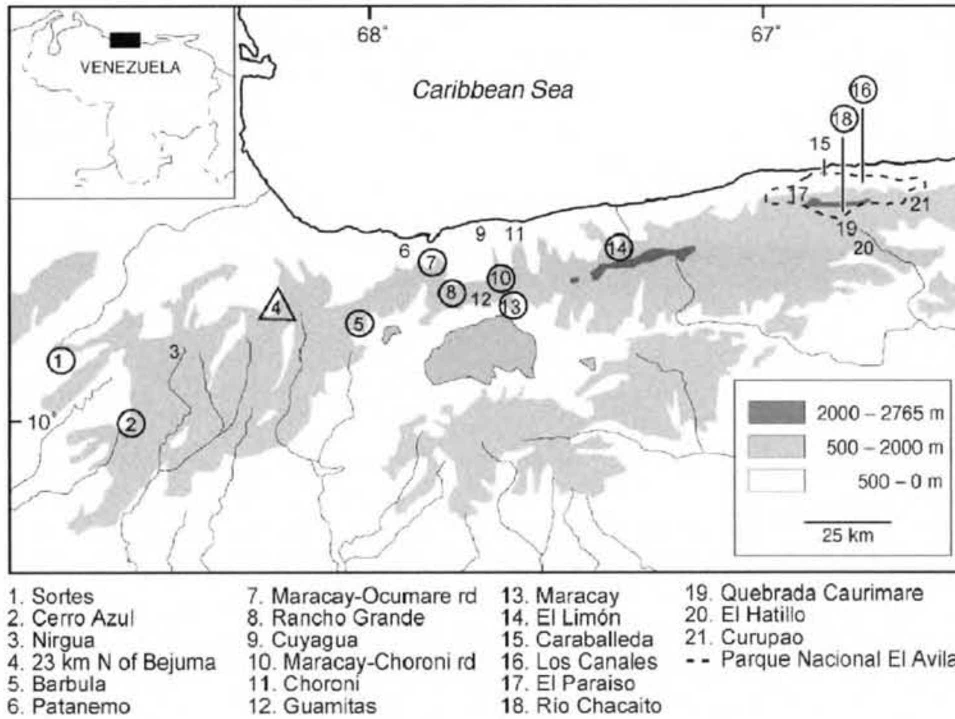

FIG. 2. Distribution of *Atelopus cruciger*. Numbers = non-overlapping collection localities; numbers in circles = collection localities of specimens examined for chytrid infection; number in triangle = locality where the infected specimen was found.

We found infection with *Batrachochytrium* in histologic sections from one specimen (USNM 259135). The superficial epidermis was hyperkeratotic and many zoosporangia of *B. dendrobatidis* were present (Fig. 3). Although most zoosporangia were empty, some contained characteristic developing stages of the fungus (see Berger et al. 1999). The infected specimen was an adult (SVL = 33.4 mm), collected at Palmichal, 23 km N of Bejuma (1465 m; 110°18' N, 68°13' W), Estado Carabobo, in May 1986. This and another specimen (USNM 259136) collected in the same locality in June 1986, constitute the last individuals of *Atelopus cruciger* to have been collected.

This is the first report of chytridiomycosis for Venezuela, and the third from South America. *Batrachochytrium dendrobatidis* has been reported from Ecuador (Ron and Merino 2000) and Uruguay (Mazzoni 2000), the latter record being from commercially raised American bullfrog (*Rana catesbeiana*). In Ecuador, five frog species were found to be infected (*Atelopus bomolochos*, *A.* sp. [aff. *ignescens*], *Gastrotheca pseustes*, *Hyla psarolaima*, and *Telmatobius niger*) with the earliest record in December 1980 (Ron and Merino 2000). Of the infected species in Ecuador, three (*A. bomolochos*, *A.* sp. [aff. *ignescens*], and *T. niger*) have not been recorded in the wild since 1994 (Ron et al. 2000). Ron and Merino (2000) concluded that chytridiomycosis was a factor involved in frog population declines throughout Ecuador. Because infection by *Batrachochytrium* has been shown to be lethal to other amphibians and to be associated with declines in other countries (Berger et al. 1998; Bosch et al. 2001; Bradley et al. 2002; Nichols et al. 2001; Speare 2001; Waldman et al. 2001), its presence in *A. cruciger* supports the hypothesis of the epidemic disease chytridiomycosis as a possible cause of the population declines.

Species that have shown chytrid associated declines often inhabit high elevation and reproduce in streams (Berger et al. 1998; Bradley et al. 2002; Lips 1999; Ron et al. *in press*). Although the infected specimen of *Atelopus cruciger* was collected at an altitude of 1465 m, the species was distributed from 40–1640 m. Local extinctions of *A. cruciger* have occurred throughout its altitudinal distribution (C. Señaris and J. Manzanilla, pers. comm.), suggesting that chytrid fungus could have affected both highland

** Questionable locality: this is the only record above 1640 m; because no more specimens have been found at similar elevations (around 2100 m), we question its validity.

and lowland populations. However, additional studies are needed to provide a more comprehensive spatiotemporal profile. Retrospective studies based on museum specimens and prospective studies sampling wild-caught frogs should be conducted in conjunction with ecological investigations to determine the distribution and impact of *Batrachochytrium* in Venezuela.

Acknowledgments.—Visits to museums in Venezuela were funded by the Panorama Small Grant Award Program of The University of Kansas, and the histological studies by the National Heritage Trust, Australia. Loans and/or specimens data were provided by US museums (CAS, CM, FMNH, KU, MCZ, MVZ, UMMZ, USNM) and Venezuelan museums (EBRG, MHNLS, MIZA, ULABG). C. Señaris, E. La Marca, J. Manzanilla, M. Salazar, J. De Marmels, A. Gardner, and P. Burrowes provided useful information. L. Trueb, E. Greenbaum, J. Pramuk, O. Torres-Carvajal, D. H. Olson, L. Berger, and two anonymous reviewers made helpful comments on this manuscript.

Chytrid Fungus in Northern and Western Cape Frog Populations, South Africa

SAMANTHA HOPKINS
e-mail: shopkins@uwc.ac.za

and

ALAN CHANNING

Chytrid fungus has been found in areas where frog populations are declining (Berger et al. 1998; Bosch et al. 2001; Lips 1999; Muths et al. 2000). Although there have been no reports of amphibian population declines in South Africa, chytridiomycosis has been detected in *Xenopus laevis* (Speare and Berger 2000). The aim of our study was to further assess the occurrence of chytrid fungus in South African frogs, specifically in the Western Cape and Northern Cape Provinces.

The Cape river frog (*Afrana fuscigula*) was chosen as the primary study species because it is widespread throughout the Cape, with populations at high and low elevation. Other species were tested for the presence of chytrid fungus, such as *Afrana vandijki* and *Strongylopus grayii*, when *A. fuscigula* could not be found or when other species were found at the same site.

Sites were chosen opportunistically, to be representative of the full area of the Western Cape Province (N = 17 sites) and as an initial sample of the Goegap Nature Reserve in the Northern Cape (N = 2). Western Cape sites varied from rivers to pools. Both sites in the Goegap Nature Reserve were natural, small, isolated pools.

Nocturnal searches were conducted with flashlights and adult frogs were captured. The fourth toe tip of the right foot was taken from each animal using nail clippers. Each toe tip was placed in a separate vial containing 70% ethanol. The nail clippers were

cleaned in 100% ethanol after each use. Dead frogs were collected, and toe tips similarly tested. In the laboratory, toe tips were embedded in hard wax, sectioned at 6m, stained in haematoxylin and eosin, and examined for the presence of chytrid zoosporangia and empty zoospores (e.g., Briggs and Burgin 2003). The presence of chytrid was confirmed by Rick Speare (James Cook University, Queensland, Australia).

Chytrid fungus was found in 36 of 85 (42%) frogs, in 2 of 5 species tested, at 10 of 17 Western Cape sites and at both Northern Cape sites (Table 1). Frogs infected with chytrid fungus were found at low (Stellenbosch 120 m) and high elevation sites (Groot Winterhoek 992 m), in rivers that flow through town centers (Stellenbosch and Swellendam), and in nature reserves (Cederberg and Groot Winterhoek) with minimum human impact. When detected, chytrid was not found in every frog per site. The number of frogs with chytridiomycosis at a site was not proportional to the number of frogs collected (Table 1).

No mass die-offs were observed in the areas where chytrid was present in the Western Cape. Most of the frogs collected appeared healthy. Two dead *Afrana fuscigula* were found, one in Groot Winterhoek and the other in Stellenbosch. Both of these had chytrid infections while other frogs taken from the same area had no chytrid infection. At the Bloukokerboom-water site in the Northern Cape, 12 dead frogs were seen, one of which was tested for chytridiomycosis along with nine frogs that appeared healthy;-all had chytrid infections (Table 1).

In other examples of chytrid infection the fungus has moved through the population and deaths have occurred in post-metamorphic frogs (Berger et al. 1998; Daszak et al. 1999). At sites in the Western Cape no mass die-offs were seen although chytrid fungus was found in a number of individuals. Apart from two dead frogs, individuals with infection appeared healthy. It is possible that the frogs tested in the Western Cape either completed metamorphosis while carrying chytrid infections, infection occurred later in the life cycle, or die-offs occurred after the site was visited. In contrast, there were many dead frogs found at one of the sites in Goegap Nature Reserve. Although chytrid may have contributed to this mortality, other factors warrant investigation because similar chytrid infections were not related to die-offs in the Western Cape. The Northern Cape area was agricultural land and is now surrounded by copper mines, hence pollutants might be present. Synergistic agents with chytrid or factors affecting immunosuppression could be involved, including toxins as well as other environmental conditions such as temperature, pH, hydration of the skin, and UV B radiation (e.g., Alford and Richards 1999, Rollins-Smith et al. 2002).

Acknowledgments.—We thank Rick Speare for help identifying infection, Gregory Crutsinger for help with the photographs, Enrico Oosthuizen for assistance at Goegap Nature Reserve, Martin Hendricks for assistance

with laboratory procedures, and Cape Nature Conservation. This research was supported by the Declining Amphibian Populations Task Force.

Tadpoles act as intermediate hosts for a great number of parasitic helminth species. The metamorphosing tadpole can serve as an efficient link between aquatic and terrestrial ecosystems by transporting larvae of helminths to terrestrial vertebrates. According to Alford (1999), parasites and commensals of tadpoles have not been studied extensively. Until recently, few studies have addressed parasites of different larval stages of amphibians in South America (Hamann and Kehr 1997, 1999; Kehr and Hamann 1995). In North America, to determine the effects of parasitism on performance of amphibians (growth, survival, locomotion), studies have been carried out under experimental conditions. These studies have addressed parasitic infection in different amphibian larval stages, juveniles, and adults (Goater 1994; Goater and Vandenbos 1997; Johnson et al. 1999).

There are very few ecological studies that examine the interaction between parasitism and other environmental factors in anurans. Parasitism may affect an individual's growth and survival. Indeed, ecologists have become increasingly interested in determining the effects of parasitism on their hosts (Minchella and Scott 1991), especially since theoreticians have shown that parasites can regulate host population size (Anderson and May 1979; May and Anderson 1979; Thiemann and Wassersug 2000a, b).

We were interested in examining the interaction of parasitism + environment on a model anuran species, *Pseudis paradoxa*, from the family Pseudidae. This species is endemic to South America and Trinidad. In Argentina the family is represented by three species: *Lysapsus limellus* Cope 1862, *Pseudis minuta* Gunther, 1859 "1858," and *Pseudis paradoxa* (Linnaeus 1758) (Kehr and Basso 1990). The three species are largely sympatric in the northern provinces of Formosa, Chaco, Santa Fé, Corrientes, and Entre Ríos (24°00'S – 33°00'S; and 56°00'W – 62°00'W) (Cei 1980; Gallardo 1987). *Pseudis paradoxa* uses permanent ponds with floating vegetation (Duré and Kehr 2001). The tadpole of *P. paradoxa* is characterized by its large size (maximum length = 230 mm; Kenny 1969) particularly compared to the size of the metamorphosed adult. This gigantism appears to be the result of extended exposure to prolactin in the tadpoles (e.g., during overwintering) (Emerson 1988). Size variability in *P. paradoxa* tadpoles from Argentinean populations has been reported by Dixon et al. (1995).

The main goals of this study were: 1) to record and analyze morphological measurements of tadpoles for different stages; 2) to determine how many helminth taxa infest *P. paradoxa* tadpoles under natural conditions; and 3) to examine the co-occurrence of parasite taxa, and the relationship between co-occurrence and tadpole morphology.

Materials and Methods.—The tadpoles studied were collected in two ponds located ca. 25 km from Corrientes City, Corrientes province, Argentina (27°30'S, 58°45'W). The distance between the ponds was 5 km. Pond 1 is a semi-permanent circular pond, ca. 60 m diameter, with a maximum depth at center of ca. 1.5 m. During the study period, the dominant vegetation was *Cyperus* spp., *Salvinia* sp., *Ludwigia peploides*, *Nymphoides* sp., and *Paspalum* sp. Pond surface vegetative cover was 20–30%. Pond 2 is a permanent circular pond, ca. 110 m diameter, with a maximum depth at center of 2 m. During the study period the dominant vegetation was *Salvinia rotundifolia*, *Pistia stratiotes*, and *Eichornia crassipes*. The pond contained a wide range of aquatic invertebrate organisms including abundant snails belonging to the family Planorbidae.

Eight tadpole samples (four per pond) were taken between 28 February and 20 March 1997. The tadpoles were captured with a 45 cm diameter dip net and maintained alive in the laboratory until they were studied (for up to two days after capture). All tadpoles were anesthetized with ether for study. The developmental stages (Gosner 1960), body length (i.e., distances from the oral disc to the beginning of the cloacal tube), oral disc width, intestine length, maximum body height, maximum tail height, maximum tail muscle height, and maximum body width were recorded for each tadpole.

The intestine, kidney, coelomic cavity, musculature, integument,

brain, and eyes of each tadpole were examined for parasites by dissection. Metacercariae were observed *in vivo* after anesthetizing the tadpoles. Parametric tests were used to establish the relationship between the morphological variables and parasite presence (Kehr 1994; Zar 1996).

We used Principal Component Analysis to 1) examine the relationship between the tadpoles' morphometric variables and the variation explained by the different combinations of them (principal components); and 2) to analyze the association among parasite taxa through a correlation matrix based on the parasite counts. Relationships between two sets of variables were investigated by performing a Canonical Correlation Analysis, one independent set composed of tadpole morphological measurements and other dependent set formed by abundance of parasites by taxa.

Statistical tests were carried out using SYSTAT 7.0 software. In order for all variables to have the same influence on the distance calculation, the variables were standardized, subtracting the variable's sample mean from each value and dividing the difference by the sample standard deviation. The standardized values have a mean of 0 and a variance of 1.

We defined parasite prevalence as the number of hosts infected with one or more parasite taxa divided by the total number of hosts examined and expressed as a percentage. Mean intensity was defined as the average intensity of a parasite taxon in the host infected with that parasite. Bush et al. (1997) detailed more information on these and other aspects of parasite terminology. The relation of variance/mean was used for determining the spatial distribution of parasites inside the host.

Results.—Twenty-seven tadpoles were collected (Pond 1: N = 14; Pond 2: N = 13). The total length of tadpoles ranged from 26.5 to 167.9 mm. Maximum body length recorded (58.3 mm) was for a stage 38 tadpole captured in Pond 2 (Table 1).

The principal components and the percentages of variation accounted for by the morphometric variables are shown in Table 2. All tadpoles collected (N = 27) were included in this analysis. The first component mainly reflects the sum of body length, body height, body width, and tail height. The second component mainly reflects the influence of oral disc width variation and the tail muscle height. The third component mainly reflects a contrast between the total length and tail muscle height.

Ten helminth parasite taxa (larvae and adults) were recorded—nine trematodes and one nematode (Table 1). The prevalence, mean intensity, minimum and maximum parasite numbers, and localization are detailed in Table 3 and 4. In pond 1 (low snail abundance, pers. obs.) the more representative helminth taxa infecting the tadpoles, in decreas-

TABLE 1. Tadpole measurements for each stage (Gosner 1960) captured in each pond type and, number of helminth parasites by taxa. N= number of tadpoles; when more than one tadpole was obtained the measurement for each stage is the mean and in parenthesis is the deviation standard (1s). TABLE 2. Results of a principal component analysis of morphometric variables of *Pseudis paradoxa* tadpoles (N = 27): coefficients of standardized measurements (each variable: mean = 0 and $s^2 = 1$), and the percentage of variation explained. Tadpoles analyzed from pond 1 + pond 2 pooled.

Coefficients	PC1	PC2	PC3
Total length	0.726	-0.180	-0.625
Body length	0.959	0.022	0.072
Oral disc width	0.169	-0.923	-0.057
Body height	0.945	0.262	0.082
Body width	0.950	0.131	0.114
Tail height	0.945	0.241	-0.005
Tail muscle height	0.596	-0.561	0.359
Percent of total variance explained	64.567	19.195	7.831
Cumulative	64.567	83.762	91.593

ing order, were: 1) *Gyrinicola* sp. (localized in the intestine), 2) Diplostomidae gen. sp. 2 (localized in the kidneys) and, 3) Diplostomidae gen. sp. 1 (localized in the kidneys). In pond 2 (high snail abundance, pers. obs.) the helminth taxa more numerous, in decreasing order, were: 1) *Gyrinicola* sp. (localized in the intestine), 2) *Catadiscus* sp. (localized in the intestine) and, 3) Diplostomidae gen. sp. 1 (localized in the kidneys).

The *P. paradoxa* tadpoles of the two ponds shared four of the ten parasite taxa recorded. In the kidneys of tadpoles three taxa of trematodes were recorded from both ponds (Diplostomidae sp. 1, 2 and Digenea gen. sp. 2), and one taxon was observed in the intestine of tadpoles in the two ponds (*Glypthelmins* sp.). The nematode, *Gyrinicola* sp. was recorded from the intestine of tadpoles from both ponds.

The principal components and the percentages of variation accounted for by the totality of helminths (pond 1 + pond 2) are shown in Table 5. The first component mainly reflects a contrast among the counts of *Glypthelmins* sp. against the sum of the counts of Diplostomidae gen. sp. 1, Diplostomidae gen. sp. 2 and *Gyrinicola* sp. The second component is mainly a contrast between the sum of the counts of *Catadiscus* sp. and *Gyrinicola* sp. against *Glypthelmins* sp. The third component mainly reflects the contrast between the counts of Digenea gen. sp. 2. against *Catadiscus* sp. The fourth component is mainly the sum of the counts of *Glypthelmins* sp. and *Gyrinicola* sp. The fifth component is mainly the sum of the counts of Diplostomidae gen. sp. 2 and *Catadiscus* sp.

Canonical correlation analysis (CCA) showed a very strong association between the two data sets, one set formed by parasite taxa (dependent variables) and another by tadpoles morphometric variables (independent variables) ($R^2 = 0.977$; RAO F = 2.027, df = 42, 69.1, P = 0.004; Table 6). In Table 6 are summarized the canonical correlations and the Bartlett test of residual correlations. The two first canonical correlations were significant, demonstrating the good associations between the two variables sets.

Discussion.—Our data agree with the observation of Dixon et al. (1995) that populations of *P. paradoxa* tadpoles are highly poly-

Table 4. Summary of helminth taxa, parasite stages, position, transmission and definitive host of parasites in the giant tadpoles of *Pseudis paradoxa* tadpoles from Corrientes, Argentina.

Helminths	Stage in tadpole	Position in tadpole	Transmission	Definitive host
Trematodes				
Diplostomidae gen. sp. 1	Metacerc.	Kidney	Skin and cloaca penetration by cercariae	Bird and mammal
Diplostomidae gen. sp. 2	Metacerc.	Kidney	Skin and cloaca penetration by cercariae	Bird and mammal
Diplostomidae gen. sp. 3	Metacerc.	Kidney	Skin and cloaca penetration by cercariae	Bird and mammal
Digenea gen. sp. 1	Metacerc.	Kidney	?	?
Strigeoidea gen. sp.	Metacerc.	Kidney	Skin and cloaca penetration by cercariae	Reptiles, bird and mammal
Digenea gen. sp. 2	Metacerc.	Kidney	?	?
Echinostomatidae gen. sp.	Metacerc.	Manicotto outside	Oral ingestion by cercariae	Bird
Glypthelmins sp.	Juvenile	Intestine	Skin and cloaca penetration by cercariae	Amphibian
Catadiscus sp.	Juvenile	Intestine	Oral ingestion by metacercariae	Amphibian
Nematodes				
Gyrinicola sp.	Adult	Intestine	Oral ingestion by eggs and larvae	Amphibian

morphic. In our tadpole samples we also recorded great variability in the measurements. About 65% of the variation observed in the tadpoles morphological features were mainly related to body features differences. Approximately 19% of the tadpole variation was produced mainly by the oral disc width. Nevertheless, only about 8% of the variation was attributed to tadpole total length.

Overall, *Gyrinicola* sp. (Nematodes) and *Catadiscus* sp. (Trematodes) showed the highest abundance and a constant frequency and, in both cases, infecting the intestine. Amphibians are the definitive host for these parasites (Baker 1987; Prudhoe and Bray 1982). For both cases, the infection depends directly upon tadpole feeding behavior because the transmission is through oral ingestion of eggs and larvae for the first taxon and metacercariae for the second. A positive correlation with the tadpole body characteristics was observed for both taxa (Table 6), probably because it is related to intestine length.

Gyrinicola sp. had the greatest infestation intensity, prevalence, and formed big nematode schools in the intestine of tadpoles in both ponds. These were the only adult helminth parasites encountered because tadpoles are their definitive host. The oxyurids (*Gyrinicola* sp.) belong to a group of parasites with simple life cycles (SLC) because they require a single host individual for their development (i.e., the eggs are directly infective to the host). Oxyurids are the only nematodes found in both vertebrates and invertebrates (Baker 1987). They commonly parasitize fish, amphibians, and reptiles.

Catadiscus sp. were only recorded in the tadpoles captured in the pond that possessed a great abundance of snails (Planorbidae) because snails are the intermediary host. Their metacercariae encyst on the substrate (e.g., roots, aquatic vegetation) and they are ingested when the tadpoles eat. According to Yamaguti (1973) the life cycle of *Catadiscus* sp. resembles that of trematodes in the genus *Megalodiscus*. The life cycles of *Catadiscus* sp. can be considered autogenic because they complete their cycles within the pond and use definitive hosts which are almost permanently restricted to the pond (e.g., frogs, turtles, snakes). This life cycle is also simple.

Two other taxa well represented in abundance in both of the ponds studied were Diplostomidae gen sp. 1 and Diplostomidae gen sp. 2. These taxa were not as well represented as *Gyrinicola* sp. and *Catadiscus* sp. For Diplostomidae gen sp. 1 and sp. 2 birds and mammals are the definitive host and inside tadpoles they are localized in the kidney (Table 4). In both parasite taxa the infection depends upon either tadpole feeding behavior and cercariae activity. The parasite penetration is through the skin and cloacae of tadpoles. The abundance of Diplostomidae gen sp. 1 and sp. 2 was positively correlated with variables related to the tail of tadpoles (swimming features) (Table 6).

The results suggest that in *P. paradoxa* tadpoles parasite infestation may be either constant or sporadic in occurrence. These results agree with Aho (1990) who suggests that communities of amphibian parasites are generally poor either from the standpoint of number of species or density of individuals that compose them. In our study the influence of pond type and tadpole morphometric features were both important factors regulating the helminth infracommunity. *Catadiscus* sp., one dominant species, was only present in the pond where snails were abundant. Recently, Kehr et al. (2000) demonstrated the relationship between biotic (parasite

TABLE 5. coexistence) and abiotic factors (pond type) on helminth infracommunity structure in populations of the frog *Lysapsus limellus*. The rate at which the host can be infected and the persistence of infection depends strongly on habitat variation, host size, and diet (Kehr et al. 2000).

Johnson et. al. (1999, 2001), under field and experimental conditions, identified a trematode parasite (*Ribeiroia ondatrae*) as the probable cause of malformations in some species of frog from North America. In our study, we did not see malformations or abnormalities in the *P. paradoxa* tadpoles.

Acknowledgments.—We are extremely grateful to M. L. Crump, R. W. Wassersug, and F. R. Hensley for helpful comments made on an earlier version of this manuscript which greatly improved it. Furthermore, we are especially indebted to M. I. Duré and F. Marangoni for helping in the laboratory and fieldwork.

A Second Set of Addenda to the Checklist of West Indian Amphibians and Reptiles

ROBERT POWELL
Department of Biology, Avila University
Kansas City, Missouri 64145–1698, USA
e-mail: powellr@mail.avila.edu

and

ROBERT W. HENDERSON
Section of Vertebrate Zoology, Milwaukee Public Museum
Milwaukee, Wisconsin 53233–1478, USA
e-mail: rh@mpm.edu

Since the publication of the most recent checklist of West Indian amphibians and reptiles (Powell et al. 1996) and subsequent addenda (Powell and Henderson 1999), new forms have been described, reevaluated, discovered for the first time in the region, or new populations have become established in areas where the species was not formerly known to occur. We use the format of the 1996 checklist in providing all of the new records that have come to our attention.

CLASS AMPHIBIA, ORDER ANURA

Family Bufonidae

***Bufo marinus*.** *Rana marina* Linnaeus 1758: 211. • WI • Linnaeus, C. 1758. Systema Naturæ per Regna Tria Naturæ, Secundum Classes, Ordines, Genera, Species cum Characteribus, Differentiis, Synonymis, Locis. Tomus I. Editio decima, Reformata. L. Salvii, Holmiae. — Burton and Echternacht (2003) reported the presence of this species on Grand Cayman and Hodge et al. (2003) noted the presence of waifs on Anguilla.

Family Hylidae

***Osteopilus crucialis*.** *Hyla crucialis* Harlan 1826: 64. • JAM • Harlan, R. 1826. Descriptions of several new species of batrachian reptiles, with observations on the larvae of frogs. Amer. J. Sci. Arts 10: 53–65. — Hedges (1996) implicitly reassigned this species from the genus *Calyptahyla* to *Osteopilus*, but see also Anderson (1996). Hass et al. (2001) provided justification based on immunological distance data, but inadvertently used the old name. The new combination was published for the first time in Powell and Henderson (2003b) and Stewart (2003).

Osteopilus marianae. *Hyla marianae* Dunn 1926:129. • JAM • Dunn, E. R. 1926. The frogs of Jamaica. Proc. Boston Soc. Nat. Hist. 38:111–130. — Hedges (1996) implicitly reassigned this species from the genus *Hyla* to *Osteopilus*, but see also Anderson (1996). Hass et al. (2001) provided justification based on immunological distance data, but inadvertently used the old name. Consequently, the new combination is published here for the first time.

Osteopilus pulchrilineatus. *Hyla pulchrilineata* Cope 1869: 163. • HISP • Cope, E. D. 1869. Seventh contribution to the herpetology of tropical America. Proc. Amer. Philos. Soc. 11: 147–169. — Hedges (1996) implicitly reassigned this species from the genus *Hyla* to *Osteopilus*, but see also Anderson (1996). Hass et al. (2001) provided justification based on immunological distance data, but inadvertently used the old name. The new combination was published for the first time in Franz (2003).

Osteopilus vastus. *Hyla vasta* Cope 1871: 219. • HISP • Cope, E. D. 1871. Ninth contribution to the herpetology of tropical America. Proc. Acad. Nat. Sci. Philadelphia 23: 200–224. — Hedges (1996) implicitly reassigned this species from the genus *Hyla* to *Osteopilus*, but see also Anderson (1996). Hass et al. (2001) provided justification based on immunological distance data, but inadvertently used the old name. The new combination was published for the first time in Powell and Henderson (2003b) and Franz (2003).

Osteopilus wilderae. *Hyla wilderae* Dunn 1925:161. • JAM • Dunn, E. R. 1926. A new tree-toad from Jamaica. Occas. Pap. Boston Soc. Nat. Hist. 5:161–162. — Hedges (1996) implicitly reassigned this species from the genus *Hyla* to *Osteopilus*, but see also Anderson (1996). Hass et al. (2001) provided justification based on immunological distance data, but inadvertently used the old name. Consequently, the new combination is published here for the first time.

Scinax rubra. *Hyla rubra* Daudin 1802:19. • LA, PRB • INT • Daudin, F.-M. 1802. Histoire Naturelle des Rainettes, des Grenouilles et des Crapauds. Levrault, Paris. — Previously known from St. Lucia in the Lesser Antilles, Rivero (1998) and Rios-López (1999) reported well-established populations in Puerto Rico. Also, note that the population on St. Maarten/St. Martín listed by Schwartz and Henderson (1991) was the result of misidentified *Osteopilus septentrionalis* (Powell et al. 1992).

Family Leptodactylidae

Eleutherodactylus adelus. *Eleutherodactylus adelus* Díaz, Cádiz, and Hedges 2003: 177. • CUB • Díaz, L. M., A. Cádiz, and S. B. Hedges. 2003. A new grass frog from pine forests of western Cuba, and description of acoustic and pattern variation in *Eleutherodactylus varleyi* (Amphibia: Leptodactylidae). Carib. J. Sci. 39: 176–188.

Eleutherodactylus rivularis. *Eleutherodactylus rivularis* Díaz, Estrada, and Hedges 2001:63. • CUB • Díaz, L. M., A. R. Estrada, and S. B. Hedges. 2001. A new riparial frog of the Genus *Eleutherodactylus* (Anura: Leptodactylidae) from eastern Cuba. Carib. J. Sci. 37:63–71.

Eleutherodactylus simulans. *Eleutherodactylus simulans* Díaz and Fong 2001: 77. • CUB • Díaz, L. M., and A. Fong. 2001. A new mottled frog of the genus *Eleutherodactylus* (Anura: Leptodactylidae) from eastern Cuba. Solenodon 1:76–84.

Family Ranidae

Rana grylio. *Rana grylio* Stejneger 1901:212. • BAH, PRB • INT • Stejneger, L. 1901. A new species of bullfrog from Florida and the Gulf Coast. Proc. U.S. Natl. Mus. 24:211–215. — Previously known from Andros and New Providence islands in the Bahamas, Rios-López and Joglar (1999) reported well-established populations in northern Puerto Rico.

Class Reptilia, Order Testudines

Family Emydidae

Trachemys stejnegeri. *Pseudemys stejnegeri* Schmidt 1928:147. • BAH, HISP, PRB, LA • Schmidt, K. P. 1928. Amphibians and land reptiles of Porto Rico, with a list of those reported from the Virgin Islands. Scientific Survey of Porto Rico and the Virgin Islands. New York Acad. Sci., Sci. Surv. Puerto Rico Virgin Isl. 10:1–160. — Breuil (2002) reported the presence of this species on Guadeloupe.

Family Pelomedusidae

Pelusios castaneus. *Emys castanea* Schweigger 1812:314. • LA • Schweigger, A. F. 1812. Prodromus Monographiæ Cheloniorum. Königsberg. Arch. Naturwiss. Math. 1:271–368, 406–458. — Iverson (1992) noted that populations on Guadeloupe previously assigned to *Pelusios subniger* were actually *P. castaneus*.

Family Testudinidae

Geochelone denticulata. *Testudo denticulata* Linnaeus 1766:352. • LA • Linnaeus, C. 1766. Systema Naturæ per Regna Tria Naturæ, Secundum Classes, Ordines, Genera, Species cum Characteribus, Differentiis, Synonymis, Locis. Tomus I. Editio duodecima, Reformata. L. Salvii, Holmiae. — Breuil (2002) reported the presence of this species on Guadeloupe.

Class Reptilia, Order Squamata

Family Anguidae

Celestus carraui. *Celestus carraui* Incháustegui, Schwartz, and Henderson 1985 and *C. anelpistus* Schwartz, Graham, and Duval 1979 were relegated to subspecific status in the "*C. warreni* complex" by Hallermann and Böhme (2002), but Powell and Henderson (2003a) disagreed, sinking *C. carraui* into the synonymy of *C. warreni* and arguing for the retention of full species status for *C. anelpistus*.

Family Colubridae

Alsophis sanctonum. *Alsophis sanctonum* Barbour 1915:78. • LA • Barbour, T. 1915. Recent notes regarding West Indian reptiles and amphibians. Proc. Biol. Soc. Washington 28:71–78. — Re-elevated to full species status by Breuil (2002).

Elaphe guttata. *Coluber guttatus* Linnaeus 1766: 385. • BAH (?), CAY, PRB, LA • INT • Linnaeus, C. 1766. Systema Naturæ per Regna Tria Naturæ, Secundum Classes, Ordines, Genera, Species cum Characteribus, Differentiis, Synonymis, Locis. Tomus I. Editio duodecima, Reformata. L. Salvii, Holmiae. — Waifs are known from the U. S. Virgin Islands, where the presence of a small breeding population is suspected (Perry et al. 2003), Anguilla (Hodge et al. 2003), Antigua (K. Lindsay 1996, pers. comm.), and St.-Barthélemy (Breuil 2002).

Hypsirhynchus scalaris. *Hypsirhynchus scalaris* Cope 1862:72. • HISP • Cope, E. D. 1862. Synopsis of the species of *Holcosus* and *Ameiva*, with diagnoses of new West Indian and South American Colubridae. Proc. Acad. Nat. Sci. Philadelphia 14:

60–82. — Re-elevated to full species status in Vidal et al. (2000).

Family Gekkonidae

Hemidactylus mabouia. *Gecko mabouia* Moreau de Jonnès 1818:138. • WI • Moreau de Jonnès, A. 1818. Monographie du mabouia des murailles, ou *Gecko Mabouia* des Antilles. Bull. Scient. Soc. Philomath. Paris, ser. 3, 5:138–139. — The presence of a breeding population was reported on Grand Cayman by Echternacht and Burton (2002).

Sphaerodactylus ariasae. *Sphaerodactylus ariasae* Hedges and Thomas 2001:168. • HISP • Hedges, S. B., and R. Thomas. 2001. At the lower size limit in amniote vertebrates: a new diminutive lizard from the West Indies. Carib. J. Sci. 37:168–173.

Sphaerodactylus parvus. *Sphaerodactylus macrolepis parvus* King 1962:16. • LA • King, F. W. 1962. Systematics of Lesser Antillean lizards of the genus *Sphaerodactylus*. Bull. Florida St. Mus. 7:1–52. — Elevated from subspecific status by Powell and Henderson (2001).

Family Iguanidae

Cyclura lewisi. *Cyclura macleayi lewisi* Grant 1941:35. • CAY • Grant, C. 1941. The herpetology of the Cayman Islands. Bull. Inst. Jamaica, Sci. Ser. (2): iv + 56 pp. — Elevated from subspecific status by Burton (2004).

Family Polychrotidae

Anolis altitudinalis. *Anolis isolepis altitudinalis* Garrido 1985:42. • CUB • Garrido, O. H. 1985. Nueva subspecie de *Anolis isolepis* (Lacertilia: Iguanidae) para Cuba. Doñana, Acta Vertebrata 12:41–49. — Elevated from subspecific status by Garrido and Hedges (2001).

Anolis breslini. *Anolis whitemani breslini* Schwartz 1980: 403. • HISP • Schwartz, A. 1980. Variation in Hispaniolan *Anolis whitemani* Williams. J. Herpetol. 14: 399–406. — Elevated from subspecific status by Glor et al. (2003).

Anolis carolinensis. *A[nolius]. carolinensis* Voigt 1832:71. • CAY, LA • Voigt, F. S. 1832. Das Thierreich, Geordnet nach seiner Organisation. Als Grundlage der Naturgeschichte der Thiere und Einleitung in die Vergleichende Anatomie. Vom Baron von Cuvier. Nach der zweiten, vermehrten Ausgabe übersetzt und durch Zusätze erweitert. Zweiter Band, die Reptilien und Fische enthaltend. F. A. Brockhaus, Leipzig. xvi + 539 pp. — The presence of a breeding population on Anguilla was reported by Eaton et al. (2001) and the presence of the species on Grand Cayman by Powell (2002).

Anolis chrysops. *Anolis marmoratus chrysops* Lazell 1964:389. • LA • Lazell, J. D., Jr. 1964. The anoles (Sauria, Iguanidae) of the Guadeloupéen Archipelago. Bull. Mus. Comp. Zool. 131:359–401. — Elevated from subspecies status by Breuil (2002).

Anolis cristatellus. *Anolis cristatellus* Duméril and Bibron 1837:143. • HISP, PRB, LA • Duméril, A. M. C., and G. Bibron. 1837. Erpétologie Générale ou Histoire Naturelle Complète des Reptiles. Volume 4. Libr. Encyclopédique Roret, Paris. — The presence of an established population on Dominica has been reported by R. Thorpe (unpubl. ms.).

Anolis desiradei. *Anolis marmoratus desiradei* Lazell 1964:387. • LA • Lazell, J. D., Jr. 1964. The anoles (Sauria, Iguanidae) of the Guadeloupéen Archipelago. Bull. Mus. Comp. Zool. 131:359–401. — Elevated from subspecies status by Breuil (2002).

Anolis kahouannensis. *Anolis marmoratus kahouannensis* Lazell 1964:382. • LA • Lazell, J. D., Jr. 1964. The anoles (Sauria, Iguanidae) of the Guadeloupéen Archipelago. Bull. Mus. Comp. Zool. 131:359–401. — Elevated from subspecies status by Breuil (2002).

Anolis leachii. *Anolis leachii* Duméril and Bibron 1837:153. • LA • Duméril, A. M. C., and G. Bibron. 1837. Erpétologie Générale ou Histoire Naturelle Complète des Reptiles. Volume 4. Libr. Encyclopédique Roret, Paris. — This form had been treated variously as a species or subspecies for some time until formally re-elevated to species status by Powell and Henderson (2001).

Anolis litoralis. *Anolis centralis litoralis* Garrido 1975:12. • CUB • Garrido, O. H. 1975. Distribución y variación de *Anolis argillaceus* Cope (Lacertilia: Iguanidae) en Cuba. Poeyana (142):1–28. — Elevated from subspecific status by Navarro et al. (2001).

Anolis mimus. *Anolis mimus* Schwartz and Thomas 1975 was allocated to the synonymy of *A. rejectus* Garrido and Schwartz 1972 by Garrido and Hedges (2000).

Anolis oporinus. *Anolis oporinus* Garrido and Hedges 2001:379. • CUB • Garrido, O. H., and S. B. Hedges. 2001. A new anole from the northern slope of the Sierra Maestra in eastern Cuba (Sauria: Iguanidae). J. Herpetol. 35:378–383.

Anolis pogus. *Anolis wattsi pogus* Lazell 1972:35. • LA • Lazell, J. D., Jr. 1972. The anoles (Sauria, Iguanidae) of the Lesser Antilles. Bull. Mus. Comp. Zool. 143:1–115. — This form has been treated variously as a species or subspecies for some time until formally elevated to species status by Powell and Henderson (2001); see also Breuil (2002).

Anolis rejectus. *Anolis vanidicus rejectus* Garrido and Schwartz 1972:517. • CUB • Garrido, O. H., and A. Schwartz. 1972. The Cuban *Anolis spectrum* complex (Sauria: Iguanidae). Proc. Biol. Soc. Washington 85:509–522. — Elevated from subspecific status by Garrido and Hedges (2000).

Anolis sagrei. *Anolis Sagrei* Cocteau *in* Duméril and Bibron 1837:149. • BAH, CAY, CUB, JAM, LA, WC • Duméril, A. M. C., and G. Bibron. 1837. Erpétologie Générale ou Histoire Naturelle Complète des Reptiles. Vol. 4. Libr. Encyclopédique Roret, Paris. — The presence of established populations on Grenada was reported by Greene et al. (2002).

Anolis schwartzi. *Anolis wattsi schwartzi* Lazell 1972:32. • LA • Lazell, J. D., Jr. 1972. The anoles (Sauria, Iguanidae) of the Lesser Antilles. Bull. Mus. Comp. Zool. 143:1–115. — This form has been treated variously as a species or subspecies for some time until formally elevated to species status by Powell and Henderson (2001); see also Breuil (2002).

Anolis terraealtae. *Anolis terrae = altae* Barbour 1915:76. • LA • Barbour, T. 1915. Recent notes regarding West Indian reptiles and amphibians. Proc. Biol. Soc. Washington 28:71–78. — Re-elevated from subspecies status by Breuil (2002).

Anolis terueli. *Anolis terueli* Navarro, Fernández, and Garrido 2001:68. • CUB • Navarro P., N., A. Fernández V., and O. H. Garrido. 2001. Reconsideración taxonómica de *Anolis centralis litoralis* y descripción de una especie nueva del grupo *argillaceus* (Sauria: Iguanidae) para Cuba. Solenodon 1:66–75.

Anolis toldo. *Anolis toldo* Fong and Garrido 2000:666. • CUB • Fong G., A., and O. H. Garrido. 2000. Nueva especie de *Anolis*

(Sauria: Iguanidae) de la región norte de Cuba oriental. Rev. Biol. Trop. 48:665–670.

Family Scincidae

Mabuya macleani. *Mabuya macleani* Mayer and Lazell 2000:871. • PRB • Mayer, G. C., and J. Lazell. 2000. A new species of *Mabuya* (Sauria: Scincidae) from the British Virgin Islands. Proc. Biol. Soc. Washington 113:871–886.

***Mabuya sloanii* complex.** *Mabuya sloanii* Daudin 1802: Figure 4. • JAM, TC, HISP, PRB, LA • Daudin, F.-M. 1802. Histoire Naturelle, Générale et Particulière des Reptiles. Tome IV. F. Dufart, Paris. — Nomenclatural change for West Indian skinks (except *M. lineolata* from Hispaniola), see Mayer and Lazell (2000), who used *Mabuya sloanii* for skinks of the Puerto Rico Bank and stated that: "The Antillean skinks formerly included in the *Mabuya* "*mabouya*" complex not dealt with in this paper (Lesser Antilles, Jamaica, Hispaniola) are best referred to as the *Mabuya sloanii* complex until their systematics can be resolved." Breuil (2002) used *M. mabouya* for most Lesser Antillean skinks, but assigned specimens from St.-Barthélemy to *M. sloanii*. He also noted that populations of both species on St.-Martín had been extirpated.

Family Tropidophiidae

Tropidophis curtus. *Ungualia curta* Garman 1887:279. • BAH • Garman, S. 1887. On West Indian reptiles in the Museum of Comparative Zoölogy, at Cambridge, Mass. Proc. Amer. Phil. Soc. 24:278–286. — Re-elevated to full species status by Hedges (2002).

Tropidophis galacelidus. *Tropidophis pilsbryi galacelidus* Schwartz and Garrido 1975:86. • CUB • Schwartz, A., and O. H. Garrido. 1975. A reconsideration of some Cuban *Tropidophis* (Serpentes, Boidae). Proc. Biol. Soc. Washington 88:77–90. — Elevated to full species status by Hedges and Garrido (2002).

Tropidophis hardyi. *Tropidophis nigriventris hardyi* Schwartz and Garrido 1975:81. • CUB • Schwartz, A., and O. H. Garrido. 1975. A reconsideration of some Cuban *Tropidophis* (Serpentes, Boidae). Proc. Biol. Soc. Washington 88:77–90. — Elevated to full species status by Hedges and Garrido (2002).

Tropidophis hendersoni. *Tropidophis hendersoni* Hedges and Garrido 2002:158. • CUB • Hedges, S. B., and O. H. Garrido. 2002. A new snake of the genus *Tropidophis* (Tropidophiidae) from eastern Cuba. J. Herpetol. 36:157–161.

Tropidophis jamaicensis. *Tropidophis maculatus jamaicensis* Stull 1928:12. • JAM • Stull, O. G. 1928. A revision of the genus *Tropidophis*. Occ. Pap. Mus. Zool. Univ. Michigan (195):1–49 + 3 pl. — Elevated to full species status by Hedges (2002).

Tropidophis morenoi. *Tropidophis morenoi* Hedges, Garrido, and Díaz 2001:615. • CUB • Hedges, S. B., O. H. Garrido, and L. M. Díaz. 2001. A new banded snake of the genus *Tropidophis* (Tropidophiidae) from north-central Cuba. J. Herpetol. 35:615–617.

Tropidophis parkeri. *Tropidophis parkeri* Grant 1941:44. • CAY • Grant, C. 1941. The herpetology of the Cayman Islands. Bull. Inst. Jamaica Sci. Ser. (2), Kingston. — Re-elevated to full species status by Hedges (2002).

Tropidophis schwartzi. *Tropidophis caymanensis schwartzi* Thomas 1963:3. • CAY • Thomas, R. 1963. Cayman Islands *Tropidophis* (Reptilia, Serpentes). Breviora (195):1–8. — Elevated to full species status by Hedges (2002).

Tropidophis stejnegeri. *Tropidophis pardalis stejnegeri* Grant 1940:119. • JAM • Grant, C. 1940. II. The reptiles. *In* W. G. Lynn and C. Grant, The Herpetology of Jamaica, pp. 61–148. Bull. Inst. Jamaica Sci. Ser. (1), Kingston. — Elevated to full species status by Hedges (2002).

Tropidophis stullae. *Tropidophis maculatus stullae* Grant 1940:121. • JAM • Grant, C. 1940. II. The reptiles. *In* W. G. Lynn and C. Grant, The Herpetology of Jamaica, pp. 61–148. Bull. Inst. Jamaica Sci. Ser. (1), Kingston. — Elevated to full species status by Hedges (2002).

Family Typhlopidae

Ramphotyphlops braminus. *Eryx braminus* Daudin 1803: 279. • CAY, LA • Daudin, F.-M. 1803. Histoire Naturelle Générale et Particulière des Reptiles. Vol. 7. F. Dufart, Paris. — Echternacht and Burton (2003) reported the presence of this species on Grand Cayman and Breuil (2002) noted its presence on St.-Martín and St.-Barthélemy.

Typhlops guadeloupensis. *Typhlops guadeloupensis* Richmond 1966:129. • LA • Richmond, N. D. 1966. The blind snakes, *Typhlops*, of Guadeloupe and Dominica with the description of a new species. Herpetologica 22:129–132. — Re-elevated to full species status by Breuil (2002).

Acknowledgments.—S. Blair Hedges brought several new records to our attention and commented on an earlier draft of this manuscript. Roger Thorpe provided an unpublished report on the occurrence of *Anolis cristatellus* on Dominica.

TECHNIQUES

Herpetological Review, 2003, 34(4), 345–348.

A Radio Transmitter Belt for Small Ranid Frogs

ERIN MUTHS
USGS-Biological Resources Division, Fort Collins Science Center
2150 Centre Avenue, Bldg C, Fort Collins, Colorado 80526, USA
e-mail: erin_muths@usgs.gov

Radio telemetry is a useful technique for gathering information about amphibians when associated caveats are applied (Bartelt and Peterson 2000). A number of designs for transmitter attachment are available for larger anurans including a harness-type attachment (van Nuland and Claus 1981) and various belt designs (Bartelt and Peterson 2000; Rathbun and Murphey 1996; Waye 2001). Attaching radios to small anurans is particularly problematic because of their mass, shape, and delicate skin. Small radios, 0.61 grams or less, are available, although battery life is usually only 2–3 wks (e.g., Holohil Systems Ltd; Carp, Ontario, Canada[1]). The issues remaining are the weight and longevity of the attachment system, ease of application to the animal, and effect on the behavior and health of the animal.

Here I describe an attachment assembly tested in the laboratory on juvenile leopard frogs (*Rana pipiens*) and used on wood frogs (*Rana sylvatica*) in the field.

The goal of the field study was to fit radio assemblies to 8 wood frogs (4 males and 4 females) and to follow them for approximately 2 wks (the life of the battery) during and immediately after the breeding season (May–early June). Male wood frogs generally breed in their second spring when they are between 34 and 40 mm snout–vent length (SVL); females generally breed in their third spring when they are between 45 and 54 mm SVL (Hammerson 1999). Currently available attachment methods were unacceptable for these small ranid frogs.

I used Holohil BD-2A transmitters (0.61 g). The transmitters were configured so that the battery was placed on top of the transmitter rather than in front of it (Fig. 1b). In earlier trials, using the belt system described by Bartelt and Peterson (2000) and the original, linear arrangement of the transmitter, frogs were unable to properly orient themselves in the water. This was because the length of the assembly system made the transmitter ride too far up on the frog's back and because the belt material was too bulky.

I used very fine craft elastic (gossamer floss, B. Toucan, Inc., US $1.64 for 5 yds) and size 14 Japanese glass seed beads in olive

Herpetological Review

Volume 34, Number 4 — December 2003

HERPETOLOGICAL REVIEW

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2004 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with VISA or MasterCard (account number and expiration date must be provided). Payment should be sent to: Theodora Pinou, SSAR Treasurer, Peabody Museum of Natural History, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Fax: (203) 432-5176; e-mail: theodora.pinou@yale.edu

Future Annual Meetings

2004 — University of Oklahoma, Norman, Oklahoma, 26–31 May (with ASIH, HL)
2005 — University of South Florida, Tampa, Florida (with ASIH, HL)

About Our Cover: *Protobothrops jerdonii*

Forested areas of southeastern Asia are home to a diverse group of pitvipers assigned to several genera. Many of these species have traditionally been placed within the genus *Trimeresurus*, but recent molecular phylogenetic studies (Kraus et al. 1996. Copeia 1996:763–773; Parkinson 1999. Copeia 1999:576–586; Tu et al. 2000. Zool. Sci. 17:1147–1157) have confirmed the presence of multiple monophyletic assemblages within *Trimeresurus* (*sensu lato*). Of these, the genus *Protobothrops* (Hoge and Romano-Hoge 1983. Mem. Inst. Butantan 44–45:81–118) comprises a group of seven species of relatively gracile pitvipers that collectively range from India eastward to China, Japan, and Vietnam.

Protobothrops jerdonii occupies areas of southern China, northeastern India, and northern Indochina. The snake on our cover is representative of *P. j. bourreti* (Klemmer, 1963), a relatively rare and narrowly distributed subspecies, occupying northwestern Vietnam (Lao Cao and Lai Chau provinces).

This specimen, photographed in situ by **Nikolai Orlov**, was found in the morning on the branch of a tree in secondary montane rainforest at 1900 m elevation in the Hoang Lien mountain region (Lao Cao Province, northwestern Vietnam). Orlov used a tripod-mounted Nikon F4 camera with a Nikkor f2.8 macro lens, two SB 28 flashes, and Fuji Sensia (100 ASA) film to record the image. To show this snake in landscape with surrounding habitat in focus, a low aperture setting of f11 was used.

Orlov and colleagues have studied this snake in the Mount Fan Si Pan area, where it occurs from 1400 to 2300 m elevation. It is semi-arboreal, active mostly at night on bushes, large boulders, and rocky slopes on the banks of waterfall streams. Basking snakes have been observed in April and May during the day following cold nights where air temperatures dropped to 10°C. Interestingly, snakes have been found at night at air temperatures as low as 11°C, being fully active and even feeding (Orlov et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 345–359. Eagle Mountain Publ., Eagle Mountain, Utah; Orlov et al. 2002. Faun. Abh. Staatl. Mus. Tierk. Dresden 23[10]:177–218). Mating seemingly takes place in April and young are born live.

Orlov is a research scientist affiliated with the Zoological Institute of the Russian Academy of Sciences in St. Petersburg. He has a long-standing interest in the herpeto-fauna of the Palearctic and eastern Asia, and has authored about 140 publications, including six monographs. He has led or participated in more than 50 collecting expeditions to areas throughout the former Soviet Union, as well as Mongolia, Vietnam, Thailand, Laos, Nepal, and India, often in cooperation with herpetologists from Goteborg University, Royal Ontario Museum, Field Museum of Natural History, and Museum of Vertebrate Zoology.

SSAR BUSINESS

Announcing the 2004 Joint Meeting of Ichthyologists and Herpetologists 26–31 May 2004

HERPETOLOGISTS' LEAGUE (HL)
AMERICAN ELASMOBRANCH SOCIETY (AES)
SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES (SSAR)
AMERICAN SOCIETY OF ICHTHYOLOGISTS AND HERPETOLOGISTS (ASIH)

Please see the insert included in current issue of *Journal of Herpetology* for information on how to register for the Joint Meeting in Norman, Oklahoma. All material normally included in the Call for Papers will be accessible on the Joint Meeting website (www.dce.ksu.edu/2004jointmeeting). The Joint Meeting website will be linked to ASIH, HL, SSAR, and AES websites. **In contrast to past years, the Call for Papers will only be mailed if requested.** Members who lack access to the internet may request paper copies from William J. Matthews, Department of Zoology, University of Oklahoma, Norman, Oklahoma 73019, USA (e-mail: wmatthews@ou.edu; fax 405-325-6202).

Herpetological Conservation Update

Herpetological Conservation is an SSAR publication series devoted to important topics in the conservation biology of amphibians and reptiles. Volume Three, scheduled for publication in 2005, will focus on **Urban Herpetology**. We are currently seeking contributions. The Editors for the volume are Dr. Robin E. Jung and Dr. Joseph C. Mitchell. For a description of this volume's scope, objectives, topics, and contribution needs, please go to http://www.ku.edu/~ssar/HConservation.html.

Seibert Award Winners for 2003 Announced

The twelfth annual Seibert Awards were presented at the 46th Annual Meeting of the SSAR in Manaus, Brazil, 26 June–1 July

2003. These awards are named in honor of Henri C. Seibert, an early and tireless supporter of SSAR (having served as an officer for over 20 years). In recognition of outstanding student presentations at the annual meeting, a single award was given in each of the following categories: Systematics (3 eligible presentations), Physiology/Morphology (5 eligible presentations), Evolution (3 eligible presentations), Ecology (10 eligible presentations), and Conservation (8 eligible presentations). All five awardees received a check for US $200 and a book from Academic Press.

The Winners.—Systematics: Matthew Brandley, Department of Biology, San Diego State University, "Inferring the Phylogenetic Relationships of Skinks (Squamata: Scincidae) using Partitioned Bayesian Analyses of DNA." Physiology/Morphology: Paula Kahn, Craig Guyer, and Mary Mendonça, Dept. of Biological Sciences, Auburn University, "Biomarkers of Stress and Immunocompetence in Gopher Tortoises: A Preliminary Study." Ecology: Nancy Schoeppner and Rick Relyea, Dept. of Biological Sciences, University of Pittsburgh, "All Cues are not Created Equal: How Predator Diets Affect Prey Behavior." Conservation: Robert Puschendorf, Frederico Bolaños, and Gerardo Chaves, Universidad de Costa Rica, "Long-term, Widespread, Taxonomic and Geographic Prevalence of Chytrid Fungus in Costa Rican Anurans." Evolution: Conrad Hoskin and Craig Moritz, Department of Zoology and Entomology, University of Queensland, "Character Displacement across a Mosaic Contact Zone in the Green-Eyed Tree Frog *Littoria genimaculata* of the Wet Tropics, NE Australia."

Honorable Mention.—Ecology: Josh Auld and Rick Relyea, University of Pittsburgh, "Having the Guts to Compete: Competitor-Induced Plasticity in Tadpole Intestines." Leigh Isaac, University of Victoria, "Characterizing the Thermal Ecology of the European Grass Snake (*Natrix natrix*) in Southeastern England." Patrick Owen, University of Connecticut, "Relative Rates of Evolution in Advertisement and Aggressive Calls in Chorus Frogs, Genus *Pseudacris*." Conservation: Joanne Hoare, Shirley Pledger, Susan Keall, Nicola Nelson, Nicola Mitchell, Charles Daugherty, Victoria University of Wellington, "Declining Body Condition Prompts Concern for the Brothers Island Tuatara, *Sphenodon guntheri*." Taylor Edwards, Cecil Schwalbe, Don Swann, Caren Goldberg, University of Arizona, "Conservation Genetics of the Sonoran Desert Tortoise, *Gopherus agassizii*."

The judges were Adolfo Amezquieta (Universidad de los Andes), Brian Crother (Southeastern Louisiana University), Chuck Crumley (Elsevier Science-Academic Press), David Bickford (University of Texas, Austin), Bobby Espinoza (California State University, Northridge), Cindy Hitchcock (USGS), Bill Magnusson (Instituto Nacional de Pesquisas da Amazônia), Joe Mendelson (Utah State University), Kirsten Nicholson (Washington University), and Marion Preest (The Claremont Colleges).

Graduate Student Reprint and Book Scavenge

Do you have extra or duplicate reprints, books, or other publications taking up valuable shelf space in your office? If so, please consider donating them to the Graduate Student Reprint & Book Scavenge, to be held at the 2004 Joint Annual Meeting in Norman, Oklahoma. This is a great opportunity for younger herpetologists to add to their research libraries. Donors can bring materials directly to the meeting or ship them ahead of time to: *Stephen C. Richter, Oklahoma Biological Survey, 111 East Chesapeake Street, Norman, Oklahoma 73019, USA; e-mail: richter@ou.edu*. Please notify Stephen if you will be bringing items with you to the meeting.

Silent Auction at 2004 Meeting

The SSAR Student Travel Awards Committee announces the Ninth Annual Frameable Art Silent Auction to be held at the 2004 SSAR meeting at the University of Oklahoma, Norman, Oklahoma. Preferred donations include herp-related photos, line drawings, prints, paintings, plates, engravings, or anything frameable, if not already framed. If you are interested in donating an item (tax deductible for U.S. residents), please contact: *Stephen C. Richter, Oklahoma Biological Survey, 111 East Chesapeake Street, Norman, Oklahoma 73019, USA; e-mail: richter@ou.edu*. Please notify Stephen if you will be bringing silent auction items with you to the meeting.

SSAR Student Travel Awards: Call for Applications

Ten awards of US $200 each are available. An applicant for a travel award must be a student and a member of SSAR, must not have previously received a travel award from SSAR, and must be the first author of a paper or poster to be presented. Application package must include: 1) letter signed by his/her major advisor or department chair that states: he/she is not completely funded for travel from another source; 2) an official copy of the poster or paper abstract to be presented; 3) a self-addressed, stamped envelope. If the research is co-authored, the applicant must also include a letter from his/her advisor stating that the work was primarily the product of the applicant. Qualified applicants are pooled and winners are drawn at random. Students from local meeting site and current members of the SSAR Travel Awards Committee are excluded from applying for a travel award. Applications must be postmarked by 15 April 2004. Award checks will be disbursed at the SSAR business meeting. Send application package to: *Dawn S. Wilson, Southwestern Research Station, P.O. Box, 16550, Portal, Arizona 85632, USA*, or for further information e-mail: dwilson@amnh.org.

SSAR Special Membership Recognition

SSAR wishes to acknowledge gratefully the following Supporting and Plenary Members. If you wish to support the Society at either of these levels, please contact Donald Schmitt at the Membership Office (ssar@memsys.com).

Supporting Members: Christopher J. Bell, James Bergan, Alvin R. Breisch, Bryant Buchanan , John P. Feeney, Douglas F. Fraser, Brian Greene, William Holmstrom, Jr., Joseph Hummer, Victor Hutchison, Richard Lardie, Tom Lott, Teresa J. & Eddie Mayfield,

Jack K. McAllister, III, Robert W. McKeever, Paul Moler, William S. Parker, Anders G. Rhodin, Robert M. Rioux, Willem Roosenburg, Hartwell Welsh, Jr., Sharon Wise, Robert A. Young.

Plenary Members: Clifton Acosta, Robert Aldridge, Noel Alt, Steven Anderson, Blain Anderson, Gilda Andrade, James Andrews, John S. Applegarth, Rudolf Arndt, David L. Auth, Ralph Axtell, Donald Ayres, Badger, Jean-Pierre Baron, Sean J. Barry, Rogerio Pereira Bastos, Aaron Bauer, Christopher K. 2003 Annual Meeting: Manaus, Brazil

The 46th annual meeting of SSAR took place from June 26 to July 1, 2003 in the Hotel Tropical Conference Center in Manaus, Amazonas, Brazil. As has been the case in recent years, the Society met jointly with the American Society of Ichthyologists and Herpetologists (ASIH), the American Elasmobranch Society (AES), and The Herpetologists' League (HL). Additionally, this year we were joined by the Neotropical Ichthyological Association, Sociedade Brasileira de Ictiologia, Sociedade Brasileira para o Estudo de Elasmobrânquios, and Sociedade Brasileira de Herpetologia. The meeting was hosted by Instituto Nacional de Pesquisas da Amazônia (INPA), Universidade Federal do Amazonas, and Associação de Ictiólogos e Herpetólogos da Amazônia.

More than 1100 herpetologists and ichthyologists (over half of them students) from at least 35 countries attended the meeting. Eleven symposia were held and almost 400 oral and 500 poster presentations were enjoyed over a very busy 6-day period. Many thanks to the local chairs, Richard C. Vogt and Ning Labbish Chao, and the hoards of volunteers for organizing and running the meeting in such a unique and special place.

Social Programs

Walter Hödl, a preeminent tropical amphibian biologist from the University of Vienna, presented this year's SSAR President's Travelogue on the evening of June 26 following an introduction by SSAR President Janalee Caldwell. In a packed room we were treated to a wonderful slide show entitled "From the Amazonian

The site of the annual meeting picnic on the banks of the Rio Negro. Photo by Dawn Wilson.

Floating Meadows to the Surumoni Canopy Crane Project: Frog Research in Amazonia." Dr Hödl's research has focused on behavioral ecology, population and acoustic biology, and reproductive behavior of frogs and salamanders. He has been coming to the Amazon since 1976, so is now well-seasoned, but admitted that his training as an alpine climber and lab biologist did rather little to prepare him for his first visit. We were treated to stories and slides of places he had been, of people who had helped him, and fountains he had bathed in! We also heard a little about Walter's "other life" filming stingless bees and ghost shrimp. Dr Hödl's presentation was wrapped up with a well-received presentation of the toe-tapping "*Phyllomedusa* Blues."

The Joint Plenary Session on the morning of June 27 began with a general welcome and introduction to the meeting from local chairs, Richard C. Vogt and Ning Labbish Chao, and local scientists and dignitaries. The ASIH Presidential Address, given by David Cannatella was entitled "AmphibiaTree: A Community-based Phylogeny of Amphibians." William E. Duellman, The Herpetologists' League's Distinguished Herpetologist, presented "In Search of El Dorado: The Neotropical Herpetofauna," and Ricardo Rosa presented the AES Presidential Address entitled "From the Amazon to Atol das Rocas: A Brief History of Brazilian Elasmobranch Studies." The traditional Group Photograph was then taken outside around the Vitoria Regia swimming pool. This year's photograph gathering outstripped even last year's (in Kansas City) in terms of heat and humidity. A busy schedule of oral and poster sessions was kicked off after lunch.

The Annual Auction, co-sponsored by SSAR and The Herpetologists' League, was held on the evening of June 30. Although the number of items available was down a little compared with recent years, energetic bidding still occurred and the auction was a great success. A canoe filled with beer undoubtedly helped drive up the bidding! An exhibit of live reptiles and amphibians native to the Amazon drew many viewers keen to see some of the local fauna. Thanks to Marcelo Gordo (UFAM) for arranging this.

The mid-meeting picnic was held on the sandy beach of the Rio Negro on the evening of June 29. The picnic featured a typical Brazilian churrasco with more food than we could have eaten in a week! Entertainment included music and dancing by "Boi-Bumbá." The social aspect of the meeting finished with the Joint Meeting Banquet on Tuesday (July 1). Once again we were well-entertained, this time by some of our own members.

Many attendees took advantage of the incredible locality and ventured far from Manaus either before or after the meeting. Full-day and half-day excursions were taken in the Manaus-Rio Negro area for those needing a break from meeting activities. Keen birdwatchers could often be seen lurking around the hotel grounds and trips to the local market were a real treat, especially for the ichthyologists.

Board Meeting and Business Meeting Summaries

Society President Janalee Caldwell called the Annual SSAR Board Meeting to order at 0810 h on June 26, 2003, at the Hotel Tropical in Manaus, Brazil. Nine members of the Board of Directors and/or the Society attended the meeting. Because of the lack of a quorum, issues were discussed but no votes could be taken. Necessary votes will be taken via email by the Board at a later date.

President Caldwell presented summaries of reports made by SSAR Board of Directors members, Committee Chairs, and Coordinators. Former President David Green reported on activities during the last six months of his Presidency. At the 2002 Annual Meeting in Kansas City, Kraig Adler and David Dennis were honored as founders of SSAR and presented with commemorative plaques designed by Jim Murphy. President Green communicated with the Board regarding the consequences of switching to biennial elections. This decision to change to biennial elections necessitates an increase in the number of Directors and a switch to 2- or 4-year terms of office. Relevant changes in the Society's by-laws were published in *Herpetological Review* (Vol. 33[3]: 163) and will be voted on by the general membership.

During President Green's term, a new set of Membership and Subscription rates was approved by the Board of Directors and compiled. Additionally, the role of the Publications Secretary was clarified to include some business oversight and foster

Tables of food were laid out for our enjoyment at the picnic, which was held on the beach of the Rio Negro. The tables were beautifully decorated with orchids and other tropical flowers. Photo by Janalee P. Caldwell.

Barbara and Al Savitzky and John Cadle enjoying a busy poster session. Photo by Dawn Wilson.

communications between the Society editors. Appointments made included Marion Preest as Secretary (replacing John Matter), Dennis Desmond as Webmaster (replacing George Pisani), John Matter as chair of the Conservation Committee (replacing Michael Plummer), Robin Jung as Editor of *Herpetological Conservation* (replacing Steve Corn), and Ron Brooks as chair of the Nominations Committee (replacing Julian Lee). Thanks are given to outgoing officers and editors for their service.

The Board approved the recommendation of a report written by Brian Crother that BioOne be used for on-line publication of the *Journal of Herpetology* and an agreement with BioOne was signed on Dec 31, 2002. President Green stepped down as President as of December 31, 2002.

President Caldwell reported that sites for the Joint Meeting have been finalized for 2004 (Norman, Oklahoma, May 26–31) and 2005 (Tampa, Florida). Plans are underway for meeting in New Orleans in 2006. A letter of invitation was received from Kelly Zamudio to hold the 50th Anniversary Year meeting in 2007 at Cornell University. Preparations for the 2004 meeting are well in hand with a budget approved, logo prepared, etc. A good turnout of SSAR members is expected.

In January, President Caldwell signed a contract with the new SSAR Webmaster, Dennis Desmond. A number of well-received changes and updates to the website have already been made. President Caldwell has recommended the formation of a web content committee.

Appointments made during the first half of 2003 include Dawn Wilson as Chair of the Resolutions Committee and Ruston Hartdegen as Chair of the Committee on Relations with Herpetologists at Zoological Parks.

With assistance from Bob Powell, the Dean E. Metter Memorial Award guidelines were completed and Joe Beatty was appointed as chair of the committee. The Board discussed whether the Award should be administered by the Grants-in-Herpetology Committee. Letters of appreciation were sent to the Bobby Witcher Society and to Dr. Metter's widow and daughter. Additionally, a letter of thanks was sent to Mrs. Robert E. Gordon acknowledging the donation of Dr. Gordon's library and stamp collection to SSAR.

President Caldwell has revised the Nominations Procedures and is compiling recent changes to the SSAR constitution and by-laws. Other documents, including Guidelines for Committee Chairs, will be revised in light of changes from annual to biennial elections. Electronic copies of the updated material will be posted to the SSAR website and transmitted to incoming officers and chairs.

Former Treasurer Robert Aldridge (for Theodora Pinou, Treasurer, *in absentia*) reported on the state of the Society's finances for calendar year 2002. The Society made a profit of \$32,794 during this period: \$18,502 in operating income and \$14,292 in realized investment income. However, as a result of the downturn in the stock market, the Society also has an unrealized loss on its investments of \$75,404. As this is a paper loss only, it will not be realized unless assets are sold before values rebound. All funds have experienced positive year-to-date returns during 2003. The Board discussed briefly a proposal to appoint a Development Officer for the Society to spearhead fundraising efforts. The decline in membership numbers noted in last year's report continues this year, particularly in the foreign individual category. Breck Bartholomew (Publications Secretary, *in absentia*) reported that income from sales of the Society's publications totaled

A Brazilian beach party with "horned lizards." Photo by Adrian A. Garda.

$58,241.

The Board discussed the status of the SSAR publications inventory and how to manage it. The inventory is currently being stored free of charge in St Louis; however, this arrangement will not continue indefinitely. Shipping the material to Salt Lake City (where the Publications Secretary is located) would be expensive and there the Society would need to pay for storage. Several suggestions were made regarding what to do with some material, including providing it free of charge to international scientists, foreign institutions, field stations, and regional herpetological societies and making the material available at nominal charge at the 2004 meeting in Norman.

Journal of Herpetology Editor, Brian K. Sullivan (*in absentia*), submitted a report indicating a number of personnel changes. Steve Busack, Rafael de Sá, Ken Dodd, John Fauth, Mike Harvey, and Paul Verrell resigned as Associate Editors during 2002–2003. They were replaced by Sharon Downes, Don Forester, Howard Whiteman, and Martin Whiting. Mike Harvey resigned from the Board of Editors and was replaced by Steve Busack.

A reduction in the submission rate in 2002 (220 as compared with 284 in 2001 and 262 in 2000) was thought to reflect: 1) the post-acceptance lag to publication; 2) an increased rejection rate; and 3) random fluctuation. The post-acceptance lag time has been reduced significantly as a result of an increase in page numbers. However, the pre-acceptance lag time still exists. The appointment of new Associate Editors and a request for electronic versions of manuscripts should alleviate this problem somewhat. Of the 220 submissions in 2002, 42 were accepted, 126 were rejected, and 52 were being revised by the authors. Compliments have been received regarding the recently implemented use of glossy paper and the inclusion of abstracts and subheadings in Shorter Communications.

Herpetological Review Editor Robert Hansen (*in absentia*), reported a 15% increase in the number of pages in *Herpetological Review* Volume 33 compared with Volume 32. He expects Volume 34 to be approximately the same size as Volume 33. This increase in page numbers has not entailed an increase in costs because the production of *Herpetological Review* is now completely electronic. The size of *Herpetological Review* grew steadily over the past few years (a 31% increase since 1999) and submissions continue to increase. The post-acceptance lag time for Natural History Notes, although down from 9-12 months to 6-9 months, is still higher than desirable. Sharyn Marks and Michael Dorcas stepped down as Associate Editors and were replaced by Michael Grace and Robert Reed. Gordon Schuett has replaced Brian Butterfield as a Section Editor for Natural History Notes.

Robert Powell (*in absentia*), Editor of the *Catalogue of American Amphibians and Reptiles* (*CAAR*), reported on the status of this publication effort. Bob noted that the 2002 contributions to *CAAR* consisted of 20 accounts (Nos. 741–760; one salamander, two frog, two turtle, eight lizard, and seven snake accounts) for a total of 81 printed pages. Color plates were included in 19 accounts. The 2003 subscription is scheduled for June (20 accounts; three salamander, four frog, two turtle, three lizard, and eight snake accounts) and Bob has tentative plans for another 20 accounts for 2004. Production costs continue to increase, primarily because of increases in the price of paper and mailing to members, but also because of costs of shipping accounts to the Publication Secretary. Bob requested a slight increase in the budget for 2004 to allow for typical page costs (including continued use of color plates) and acquisition of software upgrades. Gregory Watkins-Colwell is serving as Index Editor. Bob reported a continual struggle to receive an adequate number of accounts and further noted that the accounts he has received recently have not been geographically balanced.

Kraig Adler (Editor, *in absentia*) reported on the publication activities of *Contributions to Herpetology*. A recent publication in this series was "*Amphibians of Honduras*," by James McCranie and Larry David Wilson (February 2002). Anticipated in August 2003 is "*Islands and the Sea: Herpetological Explorations in the West Indies*," edited by Robert Henderson and Robert Powell. "*Biology of the Reptilia*, Volume 20 (Morphology)," edited by Carl Gans and Abbot Gaunt and "*Field Guide to Amphibians and Reptiles of the West Indies*," by S. Blair Hedges are expected in 2004. Beyond next year, publications will include "*Herpetological Time Travel Through the Zoo and Aquarium World*," by James B. Murphy, "*Tasks and Problems Studying the Life of Reptiles in Zoos*," by Hans-Günter Petzold, and "*Lizards of Southern Africa*," edited by William R. Branch and Aaron Bauer.

Editor of *Facsimile Reprints in Herpetology*, Aaron Bauer (*in absentia*), reported on the reprinting of "*Herpetology of Cuba*," by Thomas Barbour and C.T. Ramsden in April 2003. Expected in 2004 is "*Les Tortues de l'Indochine*," by René Bourret. "*The Herpetological Contributions of Mario Giancinto Peracca*," edited by Franco Andreone and Elena Gavetti (with an English translation of the introduction) and "*The Herpetological Contributions of John Edward Gray*" are anticipated beyond 2004. Gregory Watkins-Colwell has been appointed as Associate Editor. Aaron aims ultimately to produce two facsimile publications per year; however, for the near future he expects one per year.

Herpetological Circulars Editor, John Moriarty (*in absentia*), reported that HC 32, "*Conservation Guide to the Eastern Diamondback Rattlesnake*" will be published in August 2003. No *Herpetological Circular* is planned for 2004; however, manuscripts are being solicited for the future.

Stephen Corn (*in absentia*), former Editor of *Herpetological Conservation* reported that Volume 2 in this series, "*Ecology, Conservation, and Status of Reptiles in Canada*," has been received and is expected to be sent to the printer in Fall, 2003. Robin Jung has taken over the duties of Series Editor and will be involved with the production of Volume 2.

Reports were received from the following committees: Dean Metter Memorial Award Committee, Grants-in-Herpetology Committee, Henri Seibert Awards Committee, Kennedy Student Award Committee, Meeting Management and Planning Committee, Standard English and Scientific Names Committee, and Student Travel Awards Committee.

The Dean Metter Memorial Award Committee (Chair, Joseph Beatty, *in absentia*) has received proposals for this award and a winner will be announced in September, 2003. Deadlines for this award will be different in upcoming years and will be reported in *Herpetological Review*.

Erik Wild (Chair, *in absentia*) reported that six Grants-in-Herpetology Awards in the amount of $500 each have been made. The number of applications increased approximately 30% compared with recent years and included proposals from 12

countries other than the United States.

The Board commended Erik for soliciting proposals actively from individuals outside the U.S. They suggested that, in regard to the International Category, wording to the effect "preference will be given to students with limited access to research funds" be inserted in the call for applications. It was suggested that the posting of a sample proposal on the website might be useful to all applicants, particularly international applicants, and that a statement regarding budget items that will not be funded (e.g., salary) might be appropriate.

President Caldwell approved all requests from Erik Wild regarding changes to the wording of the advertisement in *Herpetological Review* and changes to the title page and supported the idea of electronic submission and review of proposals. The Board clarified that in the International Category the applicant must be a student, but not necessarily a Society member, and that in the Herpetological Education Category the applicant need not be a member or a student.

Marion Preest (Chair, Henri Seibert Awards Committee) reported that four awards were made at the 2002 Kansas City meeting (details published in *Herpetological Review* 33[3]:161–163). This year the (recently very large) Ecology/Evolution Category has been split in two. Although total number of participants was low this year, it is anticipated that numbers will rise next year.

Robert Gatten, Jr. (Chair, *in absentia*) reported that no Kennedy Student Award was made this year due to the lack of a clear emergence of a winner. The Board noted that information regarding the Kennedy Award should be posted to the website, and they discussed a recommendation regarding the eligibility of students for the Kennedy Student Award.

Henry Mushinsky (Chair, ASIH Meeting Management and Planning Committee) reported on the development of plans for the Manaus meeting and on a proposal regarding symposia given to each of the Societies participating in the joint meeting. The proposal recommends limiting the number of symposia sponsored by each Society to two (funded or unfunded) and limiting the length of the symposia to 1 day each.

Henry expects to receive an official invitation to hold the 2007 meeting in Minneapolis (an invitation has already been received from Cornell for the same meeting) and notes that the Societies are now being courted by potential host cities.

Brian Crother (Chair, Standard English and Scientific Names Committee) informed the Board that an update has been submitted to *Herpetological Review* and that David Green and Roy McDiarmid have been added to the committee. A suggestion was made that SSAR might consider sponsoring a field guide of North American amphibians and reptiles. It was thought that this would be a valuable alternative to the field guides currently, or soon to be, available and could be a source of funds for the Society.

Dawn Wilson, Chair of the SSAR Student Travel Awards Committee (*in absentia*) reported that 22 applications were received and ten awards will be presented at the Annual Auction in Manaus.

Coordinators' reports were received from the Elector (Maureen Kearney), Relations with Herpetologists at Zoological Parks Committee (Ruston Hartdegen), and SSAR Representative to the American Institute of Biological Sciences (Al Savitsky). Ruston Hartdegen (*in absentia*) reported on the appointment of five individuals to the committee, the development of a mission statement, and the outlining of general goals and a tentative schedule of events, including submission of an article to *Herpetological Review* detailing the scope and purpose of the SSAR Relations with Herpetologists at Zoological Parks Committee. Al Savitsky (*in absentia*) submitted a thorough report detailing his activities as AIBS representative. He attended the 2003 AIBS council and a meeting of BioOne. One issue discussed at the AIBS meeting of importance to SSAR dealt with the way in which biologists can influence public policy. It was suggested that each Society contribute a "success story" to show how basic research can serve the public interest. Also relevant was information provided about how best to ensure that letters addressed to political representatives reach their target. The BioOne meeting involved discussion of an international program, the role of library consortia, an evaluation of electronic manuscript submissions, and the long-term consequences of electronic publication for scientific Societies.

As per our agreement with BioOne, the *Journal of Herpetology* is now available online. It is too early to assess how many users of this service there are (or will be). The Board discussed making *Journal of Herpetology* available through BioOne to SSAR members who do not have access through their institutions. A charge (to cover costs and provide a small profit) would need to be made for this service. It was not clear how much use there would be of this, since these individuals would need to be members of SSAR and therefore are already receiving paper copies of the journal. It would provide early access to the journal (prior to mailing of the hard copy) and access to some back issues. A suggestion was made that a special membership category be made that only allows access to *Journal of Herpetology* electronically. This category would be less expensive than existing membership categories and could have the effect of increasing membership. The balance between a possible increase in membership and a decrease in sales of *Journal of Herpetology* needs to be considered.

The Board discussed the use of *Allen Track* to convert submissions and review of manuscripts to *Journal of Herpetology* to an entirely electronic process. This would have the effect of reducing the submission to publication lag time. Brian Sullivan is interested in the idea, but does not have the time to invest in setting up this system. A suggestion was made that we provide funds to support someone to assist Brian with the setup. Concern was expressed that conversion to a wholly electronic format makes it more difficult for reviewers to serve as copy-editors (as many currently do with hard copies of manuscripts). This then puts the job of copy editing solely on the associate editor.

There being no further business President Caldwell adjourned the meeting at 1155 h.

A sparsely attended SSAR Annual Business Meeting was held a few days later on June 29 in the Hotel Tropical. It was called to order at 1340 h by President Caldwell who then reviewed some of the issues dealt with in the Board Meeting. The only new business raised related to the upcoming World Congress of Herpetology (WCH) in Canada. Richard Wassersug reported on informal discussions held earlier in the week. Specifically, recommendations included choosing a theme for the Congress, thoroughly organizing the meeting prior to the event, increasing communication with participating societies and society members (possibly through increased website linking), and increasing representation of

individuals from areas other than North America and Europe. Concern was raised at the meeting about the continued dismantling of zoology departments worldwide. It was thought that the WCH could highlight the importance and usefulness of an organismal approach to biological research.

The meeting was adjourned at 1510 h.

— *Respectfully submitted by Marion R. Preest, SSAR Secretary*

NEWSNOTES

Southwestern Research Station Positions and Grants for 2004

VOLUNTEERS.—Approximately 30 volunteer positions are open at the American Museum of Natural History's Southwestern Research Station in Portal, Arizona. The volunteer program is run annually and offers students in biological sciences outstanding opportunities to observe and become involved with scientists doing field research. Food and lodging are provided to volunteers in exchange for twenty-four hours per week of routine chores, with the remaining time available for research activities.

The program is open to both undergraduate and graduate students; the latter may pursue their own research projects. Faculty knowing of promising students should alert them to this opportunity for professional experience toward, development of, and evaluation of their career goals. The program is open to non-students as well, particularly in the spring and fall.

Volunteers are needed between March 4 and October 31, 2004. Appointments are for part of this period, with a minimum appointment of six weeks. Applicants for spring positions (March–May) should submit applications by February 15, summer volunteers (June–August) by April 1, and fall volunteers (September–November) may apply any time.

For applications, write: *Dr. Dawn S. Wilson, Director, Southwestern Research Station, American Museum of Natural History, P.O. Box 16553, Portal, Arizona 85632, USA; phone/fax: 520-558-2396; e-mail:swrs@amnh.org.*

SOUTHWESTERN RESEARCH STATION STUDENT SUPPORT FUND.—The American Museum of Natural History awards several grants each year of approximately US $400–$800 to graduate or postdoctoral students pursuing research at its Southwestern Research Station in the Chiricahua Mountains, Portal, Arizona.

Information and application forms for this program and other Museum grant programs can be obtained by contacting: Office of Grants and Fellowships, American Museum of Natural History, Central Park West at 79th Street, New York, New York 10024-5192, USA; http://research.amnh.org/grants/index.html. Application due date: February 15, 2004. Address questions concerning the Station to: *Dr. Dawn S. Wilson, Director, Southwestern Research Station, American Museum of Natural History, Portal, Arizona 85632, USA; phone/fax: 520-558-2396; e-mail: swrs@amnh.org.*

Amphibian Monitoring Volume Translations

Russian and Spanish translations are now available for the book, "Measuring and Monitoring Biological Diversity: Standard Methods for Amphibians," published by the Smithsonian Institution Press in 1994.

The Russian version was translated by Dr. Sergei M. Lyapkov, edited by Dr. Sergius L. Kuzmin, and printed by KMK Scientific Press Ltd. The Russian translation was printed in June 2003. The cost per copy is $29 US plus shipping. Orders should be sent to Dr. Kirill Mikhailov at kmk2000@online.ru.

The Spanish version was translated by Dr. Esteban O. Lavilla, edited by Olga MacBryde, and printed by Editorial Universitaria de la Patagonia. Although the book was printed in 2001, the Editorial Universitaria de la Patagonia has not been able to distribute it, due in large part to the Argentine economic crisis. Dr. Néstor Basso has successfully acted as an intermediary with the Editorial to resolve the distribution problem. The book is now available from Bibliomania. The cost per copy is US $24.95 plus shipping. Orders should be sent to Bibliomania either at breck@Herplit.com or the Bibliomania web site http://www.herplit.com.

Slowinski Award Recipient for 2003

The Center for North American Herpetology is pleased to announce that the inaugural recipient of the Joseph B. Slowinski Award for Excellence in Snake Systematics is Thomas P. Wilcox, formerly a researcher in the Section of Integrative Biology and Center for Computational Biology and Bioinformatics at the University of Texas, Austin, and currently conducting research in Florida. The award is named for the late Curator of Herpetology at the California Academy of Sciences, who died from the bite of a krait in the jungles of Myanmar on 12 September 2001.

This fitting tribute, brought about through the generous contributions of Joe's friends and colleagues, was created as a trust in perpetuity in 2002, with the commitment to award a $500 prize annually to the biologist who published in the previous calendar year the premier scientific paper on snake systematics, an area of research to which Joe Slowinski was deeply committed.

A distinguished committee, comprised of Frank Burbrink (City University of New York, Staten Island), Brian Crother (committee chair, Southeastern Louisiana University, Hammond), and Robin Lawson (California Academy of Sciences, San Francisco), selected the paper entitled "Phylogenetic Relationships of the Dwarf Boas and a Comparison of Bayesian and Bootstrap Measures of Phylogenetic Support" (published in *Molecular Phylogenetics and Evolution*, volume 25, number 2). The paper was co-authored by Wilcox with Derrick J. Zwickl, Tracy A. Heath, and David M. Hillis (all of the University of Texas at Austin).

MEETINGS

Meetings Calendar

22–23 April 2004—Squamate Evolution and Systematics: A Conference in Honour of Garth Underwood. Linnean Society of London, UK. For information, contact janet@linnean.org.

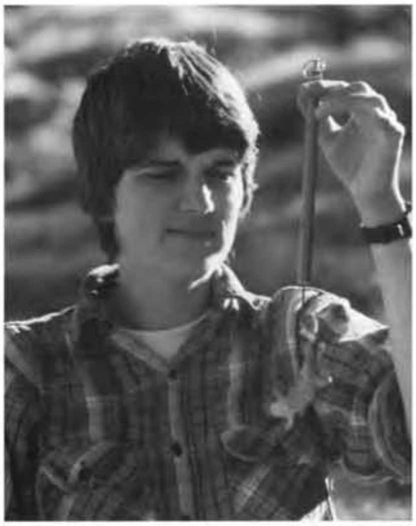
26–31 May 2004—47th Annual Meeting, Society for the Study of Amphibians and Reptiles, together with The Herpetologists' League and the American Society of Ichthyologists and Herpetologists. University of Oklahoma, Norman, USA.

15–20 November 2004—VI Symposium of Zoology, Havana, Cuba. Information: Executive Secretary: DrC. Daysi Rodríguez Batista (zoologia.ies@ama.cu) or www.geocities.com/zoologiacubana/simposio.

OBITUARIES

Herpetological Review, 2003, 34(4), 289.

Cynthia Kagarise Sherman (1950–2002)



Cindy Sherman, who published important papers on amphibian population declines and the role of diseases in them, died of pancreatic cancer in Ithaca, New York, on 16 November 2002, at the age of 52. Cindy was born in Altoona, Pennsylvania, on 6 September 1950. She graduated from Cornell University in 1972 with honors in biology for her research project completed under the mentorship of Jack W. Bradbury. At The University of Michigan, Cindy completed her PhD in 1980, under the supervision of Richard D. Alexander, with a thesis entitled "A Comparison of the Natural History and Mating System of Two Anurans: Yosemite Toads (*Bufo canorus*) and Black Toads (*Bufo exsul*)." It was here that she met and married a fellow student in the same laboratory, Paul W. Sherman, with whom she moved to the University of California at Berkeley.

Cindy returned to Cornell in 1981 as a research associate when her husband took a faculty position in the Department of Neurobiology and Behavior, where earlier she had been a student. When their two children were born, she resigned her position to focus on their welfare but continued her research informally.

In 1993, with Martin L. Morton, Cindy documented the dramatic population declines in the Yosemite toad of the Sierra Nevada of eastern California during 1971–1990. Her last paper, coauthored with D. Earl Green in 2001, has already become a minor classic in showing that chytridiomycosis and other infectious diseases, believed to be responsible for some population declines in frogs, are not a recent phenomenon, but one that goes back at least to the mid-1970s. Cindy also published on her other major research interest—aggressive behavior in dogs. She developed a thriving private consulting practice in the Ithaca area where she conducted a popular series of dog training classes and taught a new sport called "Agility."

—*Kraig Adler.*

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **Eli Greenbaum** or **Omar Torres-Carvajal**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Historical Global Ecology of Squamates

The structure of communities is largely affected by the evolutionary history of organisms. Using dietary data of non-snake squamates from the literature, the authors attempted to identify those events in the evolutionary history of large and widespread clades that contributed to the observable disparity in ecological traits among subclades. They examined how this history has affected present-day community structure and proposed three hypotheses to explain the ecological consequences of historically derived traits. The first hypothesis is that a prey shift occurred at the Iguania-Scleroglossa transition, with Iguania retaining the ancestral squamate diet (i.e., mostly ants and other noxious insects). Dietary data on Neotropical and desert lizards support this hypothesis, which suggests that part of the structure with respect to food niches in lizard assemblages is historical. The second hypothesis is that scleroglossans were better competitors than iguanians with respect to prey acquisition because scleroglossans enhanced prey handling and chemosensory-mediated prey discrimination. The third hypothesis is that iguanians and gekkotans shifted to microhabitats or times not used by most autarchoglossans. This hypothesis assumes that autarchoglossans were better competitors for food as a result of the combination of jaw prehension, mesokinesis, vomeronasal chemoreception, and high activity levels. The authors argued that a major determinant of squamate species composition and community structure is historical, without implying that recent species interactions do not contribute to community structure.

VITT, L. J., E. R. PIANKA, W. E. COOPER, JR., AND K. SCHWENK. 2003. History and the global ecology of squamate reptiles. American Naturalist 162:44–60.

Bergmann's Rule in Reptiles

Bergmann's rule hypothesizes a negative association between body size and environmental temperature. Although this association has been well studied in endothermic vertebrates, it remains unclear whether Bergmann's rule holds true for ectothermic organisms. The authors gathered data from the literature and museum specimens to investigate intraspecific body size variation relative to latitude/elevation (combined) and environmental temperature in chelonians and squamates. Nonphylogenetic and phylogenetic versions of two meta-analytical procedures (vote-counting and grand mean effect size) were used. The authors found that 83% of the species of chelonians included in the analysis were larger at higher latitudes/elevations and cooler environments. Conversely, 73% of sampled squamate species were larger at lower latitudes/elevations and warmer areas. These results suggest that chelonians follow Bergmann's rule, whereas squamates reverse it. Because the data included in this study were geographically biased (mostly Northern Hemisphere), the authors discussed the possibility that Bergmann's rule and its converse occur predominantly in temperate regions.

ASHTON, K. G., AND C. R. FELDMAN. 2003. Bergmann's rule in nonavian reptiles: turtles follow it, lizards and snakes reverse it. Evolution 57:1151–1163.

Response of Tadpole Epidermis to Thyroid Hormone

Tadpole epidermis is composed of two to three layers of cells. As thyroid hormone (TH) concentration rises during metamorphosis, cells forming the outer layers die, whereas basal cells serve as progenitors for the adult frog epidermis. The authors created transgenic tadpoles of *Xenopus laevis* to determine whether tadpole epidermal cells die autonomously as a result of TH induction, or indirectly by cell-cell interaction. TH-induced death of the epidermis of transgenic tadpoles was inhibited by expression of a dominant negative TH receptor in the epidermal cells. Although these tadpoles metamorphosed normally, a larval epidermis was retained over the developing adult epithelium, indicating that tadpole skin dies autonomously in response to thyroid hormone. This also suggests that epithelial-mesenchyme remodeling and tail resorption are not induced by larval skin in direct response to TH.

SCHREIBER, A. M., AND D. D. BROWN. 2003. Tadpole skin dies autonomously in response to thyroid hormone at metamorphosis. Proceedings of the National Academy of Sciences 100:1769–1774.

Phylogenetic Significance of the Fossil Snake *Haasiophis terrasanctus*

Different scenarios on the origin and early evolution of snakes have been proposed. Of particular interest has been the discovery of fossil taxa (*Pachyrhachis, Podophis, Haasiophis*) that combine snake-like features with plesiomorphic traits, such as relatively well-developed hind limbs. However, the phylogenetic significance of these fossils remains controversial. Some authors consider these fossils to be basal to all other snakes and suggest that snakes originated from marine mosasauroids. Other authors consider these fossils to be more advanced (macrostomatan) snakes. Rieppel et al. described the anatomy of *H. terrasanctus* in detail and reviewed the current debate on snake relationships and origins, as well as the implications of the presence of hind limbs in these fossil snakes for cladistic analyses. In spite of its well-developed hind limbs, *H. terrasanctus* has the skull of a relatively advanced snake (macrostomatan). Also, *Haasiophis* might be closely related to *Pachyrhachis*. According to the authors, they found further evidence in support of the idea that fossil snakes with well-developed hind limbs are closely related to basal macrostomatans.

RIEPPEL, O., H. ZAHER, E. TCHERNOV, AND M. J. POLCYN. 2003. The anatomy and relationships of *Haasiophis terrasanctus*, a fossil snake with well-developed hind limbs from the mid-Cretaceous of the Middle East. Journal of Paleontology 77:536–558.

Venom Diversity in Advanced Snakes

Among advanced snakes, toxinological research has focused on the venoms of Elapidae, Viperidae, and Atractaspididae. Venoms of species in the various colubrid clades have received little attention. In an attempt to determine how individual toxin families are distributed across the major advanced snakes lineages, the authors used liquid chromatography with mass spectrometry to analyze venoms of 43 species of snakes. Saliva from the reticulated python *Python reticulatus* (Henophidian) was used as negative control. The authors discovered an unexpected diversity of venom proteins in advanced snakes. Terrestrial elapids and pit vipers had a higher diversity of venom components than colubrids (except for *Psammophis* and *Heterodon*), marine elapids, and viperines. Some of the toxins detected in colubrid venoms belong to widespread toxin families shared with front-fanged snakes. The authors also found evidence of the antiquity of various toxin groups and their early appearance in advanced snakes. Additionally, they proposed to abandon the term "Duvernoy's gland," as well as the distinction between opistoglyphous and aglyphous colubrids.

FRY, B. G., W. WÜSTER, S. F. R. RAMJAN, T. JACKSON, P. MARTELLI, AND R. M. KINI. 2003. Analysis of Colubroidea snake venoms by liquid chromatography with mass spectrometry: evolutionary and toxinological

implications. Rapid Communications in Mass Spectrometry 17:2047–2062.

Water Depth and Foraging Behavior in Garter Snakes

Based on diet and foraging behavior, North American garter snakes can be divided into aquatic specialists (AS) and terrestrial-aquatic generalists (TAG). As opposed to TAG, AS are capable of crawling, striking, and visually detecting prey items underwater. These foraging behaviors have been hypothesized as adaptations of AS for feeding on widely dispersed aquatic prey. One of the predictions of this hypothesis is that intermediate species (IM) between AS and TAG (in terms of feeding on aquatic prey) shift their behavior in the direction of an aquatic specialist with increasing water depth. The author tested this prediction by comparing the aquatic feeding behavior of *Thamnophis validus* (IM) with that of *T. rufipunctatus* (AS) and *T. proximus* (TAG). A second prediction, which the author also tested using *T. validus*, is that TAG behaviors are less effective than AS behaviors in deep water. Feeding trials were carried out in a circular pool; snakes were fed rosy reds, a variety of *Pimephales promelas*. Kruskal-Wallis, Mann-Whitney U, and Wilcoxon matched-pairs signed-ranks tests were performed. The author found that *T. validus* does in fact change its behavior toward that of AS with increasing water depth. Unfortunately, the second prediction could not be fully supported or rejected. Finally, de Queiroz used a recently published molecular phylogeny of garter snakes to suggest that the facultative behavior observed in *T. validus* might represent an intermediate stage in the evolution of aquatic specialization.

Phylogeny of Advanced Snakes

True snakes (Alethinophidia) include three successively less inclusive clades: Macrostomata, Caenophidia, and Colubroidea. As currently defined, the advanced snakes clade (Caenophidia) comprises the sister taxa Colubroidea and *Acrochordus*. Phylogenetic relationships among members of Caenophidia have been subject to continued debate and conflict. Based on phylogenetic analyses of mitochondrial DNA sequence data of 98 species of snakes, the authors attempted to identify higher taxa within advanced snakes and generate robust hypotheses of relationships within and between those taxa. Supertree consensus, maximum parsimony, maximum likelihood, and Bayesian inference methods were used. The results reinforced previously supported clades, such as Viperidae, Xenoderminae, Pareatinae, Psammophiinae, Pseudoxyrophiinae, Homalopsinae, Natricinae, Xenodontinae, and Colubrinae. The position of several other advanced snake taxa was discussed. For example, the authors proposed exclusion of Xenoderminae from Colubroidea because the clade *Acrochordus* + Xenoderminae was recovered as the sister taxon of Colubroidea.

Patterns of Evolutionary Radiation in Iguanian Lizards

Existence of general properties of evolutionary radiations has been proposed, but none of these properties has been clearly identified yet. The authors used a comparative approach to identify general patterns in the relationship between cladogenesis and morphological disparity among evolutionary radiations in four clades of iguanian lizards. For each of these clades (Caribbean *Anolis*, *Liolaemus*, Australian agamids, and phrynosomatines), the authors examined historical patterns of extant subclades using molecular phylogenies. The extent to which the rate of lineage accumulation departed from a stochastic model of constant rates of diversification per lineages was estimated for each clade with the lineage diversity index. In addition, disparity-through-time plots were calculated to examine the time course of morphological diversification. Elevated levels of early diversification were identified in agamids, anoles, and phrynosomatines. Levels of average subclade morphological disparity were high in *Liolaemus*, low in agamids, and intermediate in the other two clades. The authors found that taxa with steady rates of increase in species richness (e.g., *Liolaemus*) tended to exhibit more overlap in morphological variation among subclades than taxa with high levels of early diversification (e.g., Australian agamids). They suggested that this pattern could be the result of ecological interactions, ecological opportunity, or relaxation of genetic constraints.

The Earliest Crown-Group Salamander

A new fossil assemblage containing 200 specimens of salamanders was recently discovered in the Middle Jurassic Jiulongshan Formation of Inner Mongolia, China. Assessment of fossil age was based on biostratigraphic analysis of insect and vertebrate assemblages. The remarkably well-preserved salamanders were described as *Chunerpeton tianyiensis*, a new species of Cryptobranchidae. These specimens represent the earliest known record of crown-group urodeles. The 180 mm holotype retains juvenile features, such as short external gills. Presacral vertebrae with unicapitate ribs, reduction in the number of rib-bearing anterior caudal vertebrae, and absence of lachrymal bones

are some of the derived characters that the new species shares with living cryptobranchoids. Based on the age of the new taxon and distribution of other fossil taxa, the authors hypothesized an Asian origin of cryptobranchoids (Cryptobranchidae and Hynobiidae).

ZOO VIEW

There are three major living herpetological collections in Russia: Moscow Zoo, Leningrad Zoo, and Tula Exotarium.

The Moscow Zoo is supported by the city but is viewed as a national institution. Over the years, it has had partial control over the dispersal of monies to other Russian zoos and acted as a clearinghouse for inventories and conservation efforts. The Zoo was started by a Board of Trustees from a nearby university for research and educational purposes, with public attendance as an added responsibility. The herpetological department has had a rich history which is presented here by curator Sergei Kudryavstev and his assistant Sergei Mamet.

The staff at the Leningrad Zoo (St. Petersburg), known as Leningradskii Zoopark, has published papers on captive management. Yuri Lukin is Chief of the Dept. of Herpetology and Eugeny Kamelin is the Herpetologist. According to *International Zoo Yearbook* (1998:Volume 28), composition of the collection was 76 taxa of reptiles with 252 specimens and 3 taxa of amphibians numbering 8.

In the late 1970s and 1980s, V. A. Igolkina reported on feeding activity in captive animals, incubation of reptile eggs and early ontogenesis of snakes, and captive breeding of snakes such as Lebetine vipers (*Vipera lebetina turanica* and *V. l. obtusa*) in the Leningrad Zoo. Kamelin and Lukin have investigated captive maintenance and breeding of the Central Asia cobra (*Naja oxiana*) and hybridization of *Vipera schweizeri* and *Vipera lebetina obtusa*.

Founded in September of 1987, the Tula Exotarium, located approximately 200 km south of Moscow, has specialized in research on reproductive biology, taxonomy, ecology, and principles of captive management of amphibians and reptiles. Many specimens are maintained in the off-exhibit laboratory. The collection is impressive: Asian arboreal snakes (*Boiga, Rhynchophis, Dinodon, Ahaetula*, some *Elaphe, Philodryas*, and African *Toxicodryas*); terrestrial Asian snakes (*Elaphe* sensu lato; *Spalerosophis, Coluber, Rhabdophis, Oligodon, Lycodon*, and others); kingsnakes (*Lampropeltis*) and other North American colubrids; Euro-Asian rat snakes; Asian vipers (*Trimeresurus, Protobothrops, Ovophis, Tropidolaemus*, and *Azemiops*); European and Caucasian vipers (*Vipera*); pythons and boas (*Morelia, Corallus, Sanzinia, Candoia, Python, Liasis, Leiopython, Antaresia, Boa, Acranthophis, Epicrates, Eunectes, Eryx*, and others); geckos and eublepharids (*Gekko, Rhacodactylus, Uroplatus, Gehyra, Ptychozoon, Eublepharis, Hemitheconyx, Coleonyx, Goniurosaurus*, and others); agamas and skinks (*Pogona, Physignathus, Tiliqua, Corucia, Tribolonotus, Eumeces*, and others); chelonians; and amphibians (*Polypedates, Theloderma, Ichthyophis*). In 2002, the collection included 408 species, subspecies, and forms of reptiles and 30 species of amphibians.

The Exotarium staff members are specialists responsible for specific tasks, rather than generalists as in many zoos. This group is led by Sergei Ryabov, founder of the Exotarium. Many taxa have been bred and results published: Stuart's milk snake and other kingsnakes, rare Southeast Asian ratsnakes, white-lipped python, six species of *Boiga*, rough-scaled sand boa, prairie kingsnake, Jalisco milksnake, and ashy pitviper (*Trimeresurus puniceus*), western hog-nosed snake, two species of geckos (*Paroedura, Goniurosaurus*), bearded dragons, and the green tree python. Other reproductive studies are in press: Trans-Pecos rat snake, Euro-Asian group of ratsnakes, Lotiev's viper, black mangrove snake (*Toxicodryas blandingi*), Central American rat snake (*Elaphe flavirufa*), Chinese bamboo rat snake, green-eyed gecko (*Gehyra marginata*), New Caledonian bumpy gecko (*Rhacodactylus auriculatus*), and scarlet kingsnake. Additional information may be found in Ryabov (2001. The Exotarium—Snake Centre in Russia. Litteratura Serpentium 21:40–46; 2002. The Tula Exotarium. Exso [Kiev, the Ukraine] 1:45–47).

One problem encountered by Russian authors is that their names might be changed during translation and editing into English, such as Kudryavtsev (= Kudrjavtsev in English), and Vassiliev (= Vasiliev or variations in English).

SSAR Webmaster Dennis Desmond prepared the photographs.

History of Moscow Zoo's Herp Department

SERGEI V. KUDRYAVTSEV
and
SERGEI V. MAMET
Department of Herpetology of Moscow Zoo
Moscow Zoo, B. Grouzynskaya 1, 123242, Moscow, Russia
e-mail: svkmzpmsk@mtu-net.ru

When the Moscow Zoo opened in 1864, a few reptiles were housed in various pavilions, mainly at the Aquarium. On occasion, specialized exhibits were created and the number of reptiles increased to as many as 10 species and 50 specimens. However, a formalized Reptile Department was founded in 1926, when an Artificial Mountain Complex was constructed in the so-called New Territory, where the Terrarium was incorporated on the second and third floors. After the official opening in 1927, the reptile collection grew to ca. 70 species and remained at that level for many years. During World War II (which is known as the Great Patriotic

Terrarium-Aquarium building at Moscow Zoo, 1877

War in Russia, 1941–1945) the herpetological collection was nearly disbanded. It is likely that the Terrarium was the only herpetological zoo facility to ever have anti-aircraft artillery placed on the roof during these troubled times.

Many distinguished biologists worked in the Moscow Zoo Terrarium during the period 1930–1950:

Alexey M. Sergeiyev—honorary member of Moscow State University, specializing in the evolution of reptiles. He died at age 31 in Stalin's labor camps.

Roman Khecin-Lourie—geneticist known world-wide and a corresponding member of the Academy of Science of USSR.

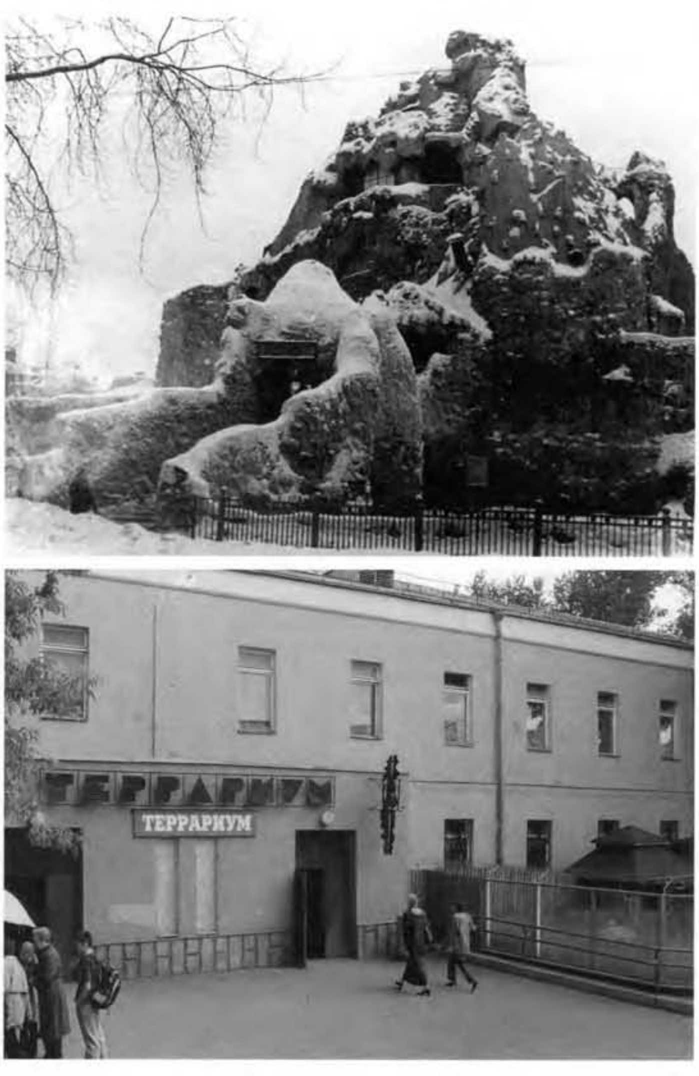
Ilja S. Darevsky—(1962), Head of Laboratory for Ornithology and Herpetology of Zoological Institute of Russian Academy of Science, corresponding member of Russian Academy of Science, professor at University of California, and professor at Armenian Institute of Zoology;

Valentina F. Orlova—from 1962, Curator of Herpetological Department of Zoological Museum of Moscow State University.

The zoo staff was equally distinguished. During the period 1946–1980, the Curator of Reptiles was Zoja N. Kovaleva. At that time, the reptile collection consisted mainly of common species but no scientific research was conducted. Vladimir Y. Frolov occupied the post between 1980–1985 and later became Assistant Director for Zoological and Veterinary matters. His successor was Sergei V. Kudryavtsev, who began working in the Department in 1981. In 1987 Sergei V. Mamet became Assistant Curator of Herpetology. The next year, the leading specialist on reptile disease in Russia, Dmitry B. Vassiliev, joined the Department.

Current Reptile Department staff members (left to right): Ludmila V. Ganina, Oleg V. Shoumakov, Sergei V. Mamet, Sergei V. Kudryavtsev, Andrei O. Bochkarjev, Dmitry B. Vassiliev, Natalja M. Soudina, Vladimir V. Fedin. Two members are missing (Tatyana V. Latysheva and Alexander V. Kouznetcov).

In 1989, the reptile collection was moved to an old, reconstructed two-story building. A rather small exhibit area allows only about 20% of the present collection to be shown. The rest of the facility is used for breeding and research purposes. The 1980s were the most active and fruitful period for herpetology at the Zoo. The collection grew dramatically and in late 1990s consisted of 226 species and 846 specimens, both common and rare. Department staff members were involved in quite a number of scientific research projects, together with colleagues at the Institute for Nature Conservation, Zoological Institute of Russian Academy of Science, zoological organizations of various Soviet Republics, and elsewhere. Researchers focused on ecology and reproductive biology of many rare amphibian and reptile species of USSR. Thus, impressive successes were attained, aimed at study of reproductive biology of nearly all rare species of vipers and ratsnakes (*Elaphe*) of USSR and of many rare Boidae. For the first time, the Central Asian cobra (*Naja oxiana*) was bred in captivity, and captive breeding of the Caspian desert monitor (*Varanus griseus caspius*) occurred at the Zoo. Over 170 scientific and popular articles, as well as several books, were published during that period. Numerous field surveys—Central Asia, Caucasus, Far East, and other regions of USSR—were conducted. In the late 1980s and early 1990s, department staff members participated in numerous herpetological studies, including the Ryukyu Archipelago (Japan), East, West and South Africa, Vietnam, Cambodia, Indonesia (Java, Sumatra, Irian Jaya), and the USA. Also, during those exciting years, many international contacts were established with colleagues from over 30 countries and at institutions such as Instituto Butantan (Brazil), Japan Snake Institute, Razi Institute (Iran), Queen Saovabho Memorial Museum (Thailand), and the National Museum of Kenya.



Top: Moscow Zoo Reptile House, 1972. Bottom: The present-day Reptile House, 2003.

During the last several years, the main research interest has been studying reproductive biology and in developing methods for long-term captive husbandry of rare and problematic species of venomous snakes found throughout the world. Herpetology at the zoo has declined recently as there have been severe financial problems. It is unlikely that funds will be available to construct a new reptile house in the near future. The size of the herpetological collection is decreasing; as a result, research has diminished as well.

Research programs

In situ studies and captive breeding of rare and problematic reptile species of Central Asia.—In the course of this research (1981–1993) the first complete studies on captive breedings of the Central Asian cobra (*Naja oxiana*) and certain species of the family Viperidae were achieved (Kudryavtsev et al. 1991); data on reproduction of the desert monitor (*Varanus griseus caspius*) was obtained (Bozhanskii et al. 1998); and ecology and zoogeography of numerous common reptile species of that region such as Central Asian tortoise *(Agrionemys horsfieldi*) (Makeev et al. 1994) were investigated. Other studies included:

Aspects of captive maintenance and breeding of rare frog and salamander species of the former USSR (Uteshev et al. 1986);

In situ studies and captive breeding of rare vipers of the former USSR, mainly of the genus *Vipera* (*Vipera ammodytes transcaucasiana, V. dinniki, V. kaznakovi, V. latifii, V. lebetina, V. raddei, V. wagneri,* and others) (Kudryavtsev and Mamet 1998b);

Studies on captive maintenance and breeding of rare ratsnakes of the genus *Elaphe* found in the former USSR and adjacent countries–*Elaphe climacophora, E. quatuorlineata, E. mandarina, E. moellendorfii, E. persica,* and others (Mamet 1999);

Studies on captive maintenance and breeding of cobras of the genus *Naja* and related elapids: *Aspidelaps, Boulengerina, Bungarus, Dendroaspis, Haemachatus, Ophiophagus,* and *Oxyuranus* (Vassiliev and Kudryavtsev 1996; Vassiliev 1997; Vassiliev et al. 1999; Kudryavtsev et al. 2001);

Ecology and captive propagation of rare and problematic Boidae species of Southeast Asia and Pacific region: *Apadora papuana, Chondropython viridis, Liasis albertisii, L. amethistinus, L. mackloti, Morelia boeleni, Python curtus breitensteini, P. curtus brongersmai, P. molurus pimbura, P. timorensis,* and others (Kudryavtsev et al. 1995; Vassiliev et al. 1997; Kudryavtsev and Mamet 1998a);

Ecology and captive propagation of rare and problematic Boiginae species of Southeast Asia and Pacific region (Shumakov 2002);

Studies on ecology and captive propagation of rare and problematic pitvipers of Southeast Asia: *Gloydius, Ovophis, Protobothrops, Trimeresurus,* and others (Kudryavtsev et al. 2002);

Studies on ecology and captive propagation of African bush vipers (*Atheris*) and related species (Vassiliev et al. 1999).

Some preliminary results of the research programs described above were published in *Terrestrial Snakes of the Soviet Union* (Kudryavtsev and Mamet 1989) and *Keeping and Breeding in Captivity Snakes of Russia and Adjacent Countries* (Kudryavtsev, Mamet, and Proutkina 1993).

POINTS OF VIEW

Herpetological Review, 2003, 34(4), 295–302.

On the Snake Hemipenis, with Notes on *Psomophis* and Techniques of Eversion: A Response to Dowling

CHARLES W. MYERS
American Museum of Natural History, New York, New York 10024, USA
e-mail: myers@amnh.org

and
JOHN E. CADLE
Chicago Zoological Society, Brookfield, Illinois 60513, USA
e-mail: jocadle@brookfieldzoo.org

Dowling (2002) recently commented on what he considered to be erroneous descriptions of snake hemipenes and made unsupported assertions concerning the genera *Psomophis* and *Siphlophis*. We here reject his pronouncements on the hemipenial morphology of *Psomophis* and provide additional details; the matter of *Siphlophis* is separately treated by Zaher and Prudente (2003).

Dowling's commentary reveals entrenched opinions that have led us also to review methods of study, particularly the techniques of everting hemipenes of both freshly killed snakes and of museum specimens. There is room for improvement and experimentation, but the procedures are not as difficult as suggested by Dowling.

The reader should keep in mind our distinction that a "fully everted" hemipenis is not necessarily "maximally expanded [or] inflated." A fully everted organ has all surfaces and structures visible, including the terminus or termini of the sulcus spermaticus. A maximally expanded hemipenis is fully everted *and* is inflated to the fullest extent allowed by its original elasticity, which may or may not be regained when working with preserved specimens. As with a balloon, there are imperceptible degrees of inflation, resulting mainly in a changing circumference. This has little taxonomic import unless hemipenial topography is noticeably different at maximal inflation—owing either to differential expansion in fresh tissue or failure to regain sufficient elasticity in a preserved retracted organ. It should be realized that the extent of hemipenial eversion and expansion attained in the female's cloaca is unknown.

Psomophis

Psomophis is a tightly knit genus containing three species of small South American xenodontine colubrids that share a novel type of hemipenis (Myers and Cadle 1994). The two heads of the bicapitate hemipenis bear large papillae that terminate in minute spinules. These spinulate papillae appear to be disposed on calyces on the retracted organ, but the appearance of calyculation may disappear completely when the organ is everted. The everted hemipenes of *Psomophis* also are atypical of capitate or bicapitate organs in that the capitula face almost completely toward the sulcate side (Figs. 1, 2); each capitulum is visible in profile but shows only as a papillate edge or underside of an upturned flap around the nude asulcate side of each lobe.

Dowling (2002:13) disagreed with the last feature mentioned above. He bluntly asserted that his examination of the hemipenis of *Psomophis genimaculatus* that was figured in Myers and Cadle (1994:Fig. 3) "showed the hemipenis to be far from 'fully everted,' and so badly distorted that the drawing showed an apical (rather than a sulcate-side) view of the partly-everted lobes." We here provide photographs (Fig. 1) of the same hemipenis to supplement the original drawing and to demonstrate the fallacy of Dowling's assertions.

The hemipenis in question (Fig. 1) had been *fully* everted and probably maximally inflated by the collector; the branches of the sulcus spermaticus do not disappear into the lobes but are seen (when the sulcus walls are parted with fine teasing needles) to

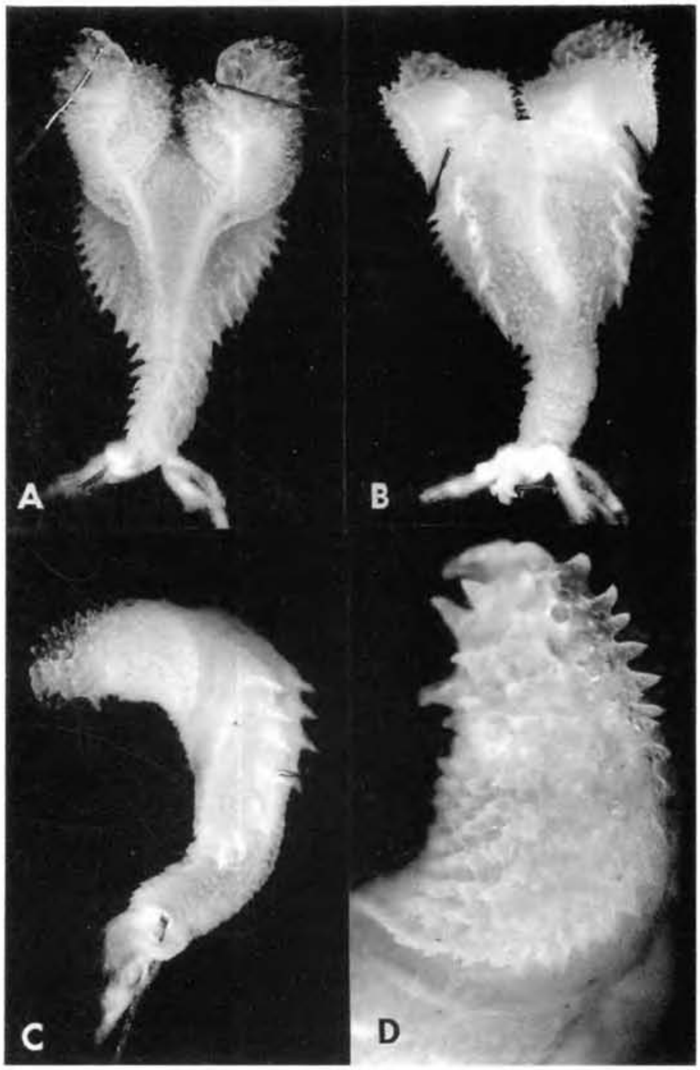

FIG. 1. The fully field-everted hemipenis of *Psomophis genimaculatus* (USNM 331437) thought by Dowling (2002:12) to be incompletely everted and "badly distorted". **A.** Sulcate view of organ restrained by minuten pins in straightened position (x4.7). **B.** Asulcate view of organ in nearly straight position (x4.7). **C.** Side view of unrestrained organ showing strong recurvature, possibly caused by tension of an unrelaxed, unsevered retractor muscle at the time of preservation (x4.7). **D.** Enlarged side view (x11.7) of capitulum showing ornamentation of large, soft papillae, which have minutely spinulate tips. Each capitulum (head) faces the sulcate side of the organ, leaving the nude asulcate side of the lobe framed distally and laterally by a papillate fringe (as figured in Myers and Cadle 1994).

terminate abruptly on the surface of the fully expanded capitula. The hemipenis is "distorted" only in the sense that, as mentioned in the original description, it is strongly recurved (Fig. 1C), although flexible enough to straighten (Fig. 1A). Field-everted hemipenes were available for no other specimen of *Psomophis* (retracted organs were described for each species). For purposes of best showing distribution of micro-ornamentation and shape of the everted hemipenis, both sulcate and asulcate sides of the organ were drawn in straightened views by Edmond V. Malnate, an artist-scientist experienced in hemipenial interpretation. We agree with Dowling that relationships "cannot be determined" from Malnate's "beautiful (but unidentifiable) drawing"—but only because the morphology of the hemipenis itself does not convincingly relate *Psomophis* to any other genus!

Although Dowling cited Zaher (1999) on other matters, he inexplicably failed to notice that Zaher had corroborated the general physiognomy of the *Psomophis* hemipenis in text discussion and with photographs of organs that Zaher had everted from preserved specimens of *P. genimaculatus* and *P. joberti* in the collection of the Instituto Butantan (Zaher 1999:71, 147, Fig. 74). These manual laboratory eversions were difficult owing especially to the extremely narrow base of the *Psomophis* hemipenis; although the photographs show distally complete eversions, the lobes are not expanded to maximum width. We have examined Zaher's preparation of *P. joberti* and provide new photographs in Figures 2–3.

The hemipenial lobes are relatively short and broad in *Psomophis genimaculatus* (Fig. 1). When the edges of the lobes of the field-everted hemipenis of *P. genimaculatus* are raised toward the horizontal plane, the lobes are seen to be nearly as wide (> 90%) as long (length as measured on medial side in sulcate view). Because of the soft drooping lateral edges, capitulum width is better visualized from the published drawing (Myers and Cadle 1994:Fig. 3 [= about x6.3, not "x3.6" in caption]) than in photographs of the same organ (e.g., Fig. 1A).

The lobes of the organ everted from a preserved specimen of *Psomophis genimaculatus* are noticeably narrower in photographic comparisons, appearing to be only about 60% as wide as long (compare Fig. 1A with Fig. 74 [lower right] in Zaher 1999). Differential expansion of fresh lobular tissue evidently accounts for the branches of the sulcus spermaticus appearing relatively shorter in the more fully expanded field-everted organ (see below).

The *Psomophis* organs manually everted from preserved specimens by Zaher show relatively shorter hemipenial lobes in *genimaculatus* than in *joberti*, with corresponding differences also in the lengths of the sulcus branches (see Zaher 1999:Fig. 74). Differences in lobe length in *Psomophis* had been suggested by comparison of retracted organs, the lobes of which varied from about 30% of hemipenis length in *genimaculatus*, to 33% and 40% in *joberti* and *obtusus*, respectively (Myers and Cadle 1994:11–12). The branches of the sulcus spermaticus extend virtually to the tips of the lobes in the retracted condition, but differential tissue expansion causes them to terminate more proximally in the everted condition. And the branches appear relatively shorter in the fully expanded organ of *genimaculatus* (Fig. 1A) than in the incompletely expanded one shown in Zaher (1999:Fig. 74).

Width of everted hemipenes cannot be estimated from the retracted condition, nor can interspecific differences in width be reliably judged by comparing lab-everted and field-everted

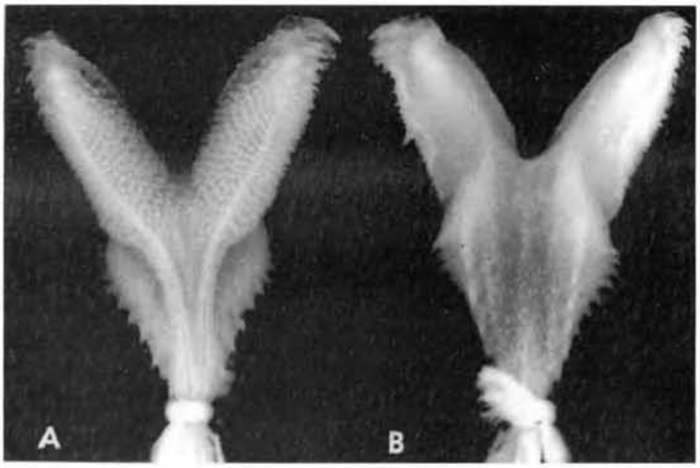

FIG. 2. Hemipenis of *Psomophis joberti* in sulcate and asulcate view, x3.9, prepared by H. Zaher from a preserved specimen (IB 36437). The organ is fully everted but incompletely expanded.

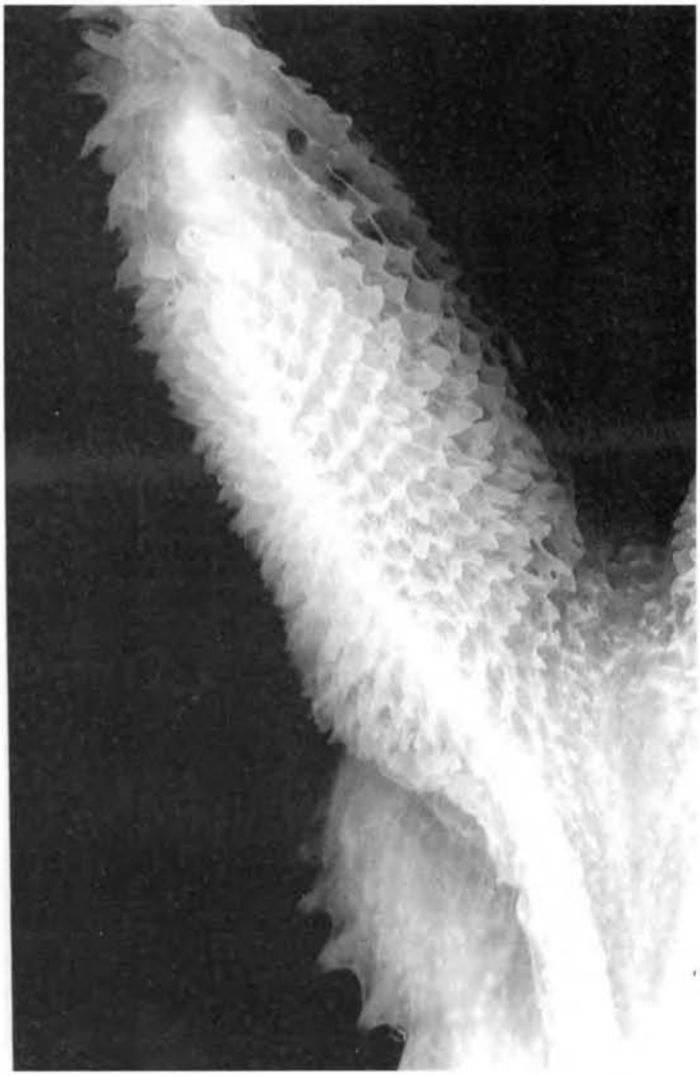

FIG. 3. Enlarged view (x13.7) of capitulum of *Psomophis joberti* (left lobe in Fig. 2A), showing arrangement of spinulate papillae on weak transverse folds. The interconnecting hairline vertical folds probably would disappear in a maximally expanded fresh eversion.

hemipenes. In any case, both the laboratory and field-eversions show clearly that in *Psomophis* the capitula face toward the sulcate side of the hemipenis.

Although Myers and Cadle (1994) and Zaher (1999) were in agreement (*contra* Dowling) over the general appearance of the everted *Psomophis* hemipenis, they differed in their interpretation of calyculation. Myers and Cadle (1994:13) noted that, on first inspection, the retracted organs of each species "appear to be calyculate with exceptionally large papillae, but the papillate surfaces are acalyculate on the everted hemipenis [of *Psomophis genimaculatus*, which] had but weak indications of tissue folds connecting single rows of spinulate papillae." In addition to loss of sharply distinct longitudinal (vertical) folds, it was observed that the transverse folds of tissue could be "flattened by micromanipulation with fine teasing needles," quite unlike normal calyces whose walls retain their rigidity at all times. Although Myers and Cadle noted that these weak folds might be vestigial calyces, they suspected that "they simply represent a method of folding expansible tissue when the *Psomophis* hemipenis is inverted for storage." Consequently the term *pseudocalyces* was coined for these transient structures (we subsequently saw that this term had been used previously by Broadley [1980:493, Pl. IIA] for markedly anastomosing flounces on the elongate, noncapitate hemipenes of two species of the African genus *Prosymna*).

The two organs everted by Zaher from preserved specimens of *Psomophis genimaculatus* and *P. joberti* retained indication of weak but thin and sharply defined longitudinal or vertical folds that connect the transverse rows (Zaher 1999:71); the retention of both vertical and transverse folds in the everted state can be visualized from an enlarged photograph (Fig. 3). Zaher interpreted these faint folds as vestigial calycular walls and noted that they are most evident "proximally near the medial edge of each capitulum." However, comparison with the field-everted hemipenis (Fig. 1) suggests that the thin, hairline vertical folds retained in Zaher's preparations would have become obliterated if further expansion of the lobes had been possible.

Since calyces are probably plesiomorphic among xenodontine and dipsadine snakes, Zaher's belief that the "pseudocalyces" represent vestigial calyces is not an unreasonable interpretation. Furthermore, along with Zaher, we suspect that evolutionary loss of the longitudinal or "vertical" walls of calyces probably explains the evolutionary origin of transverse "flounces" on the capitula of many colubrid snakes, some of which have both calyces and flounces on the same organ (e.g., some *Helicops*, see Zaher 1999:61). The everted hemipenis of *Psomophis*, with a transverse alignment of papillae and virtual absence of interconnecting vertical folds, might be in a stage nearly intermediate between calyculation and flouncing—*if* the pseudocalyces are in fact vestigial calyces, which is an open question.

The large spinulate papillae on the capitula of *Psomophis* hemipenes are doubtless synapomorphic for the genus, but it is uncertain whether they are modified "true papillae" (Zaher, 1999:71) or possibly "spines in which mineralization (an ontogenetic event) has been almost entirely arrested" (Myers and Cadle 1994:13). The first interpretation is probable if the structures rise from vestigial calyces, whereas the latter would be consistent with an origin from a hemipenis that was distally spinose. In at least one colubrid, *Geodipsas laphystia* (Madagascar), the ontogeny of spine mineralization proceeds from proximal to distal for the entire organ, and from tip to base for individual spines (Cadle 1996b:43–44). This would be consistent with Myers and Cadle's suggestion that the spinulate papillae of *Psomophis* might be spines in which mineralization has been arrested. Except for mineralized papillae (spinules) on the calyces (especially basal calyces) of many snakes, spines normally are not found on the heads of capitate hemipenes, although a single indisputable spine extends from among the spinulate papillae on each capitulum of the hemipenis of *Psomophis joberti* (Myers and Cadle 1994:12–13; Zaher 1999:71); one of these spines can be seen extending from midway along the edge of a capitulum in Fig. 2B.

The method of capitation and ornamentation of the *Psomophis* hemipenis is unusual and not clearly homologous with the conditions in other Neotropical snakes (although the sulcate-side orientation of the capitula is at least approached in some other Xenodontinae). Additionally, we know of no other instance in which pseudocalyces or calyces disappear during eversion and full expansion of the hemipenis.

Techniques of Study and Eversion

Edward Drinker Cope called attention to the systematic importance of snake hemipenes in the late 19th century. His data were derived from retracted genitalia, each of which was "laid bare *in situ* and split lengthwise along the exposed (inferior) middle line before it is removed [which is] necessary to avoid cutting it along the sulcus" (Cope 1895:190). Cope's classic 1895 paper included succinct summaries of hemipenial anatomy and variation, as illustrated by 234 elegant interpretive drawings of retracted organs.

With eventual widespread use of hypodermic syringes for preservation, it slowly became commonplace in the following century to evert hemipenes in the field by injecting alcohol (later formalin) into the tail base. Finally, more than 60 years after Cope's (1895) classic survey of diversity revealed in the anatomy of retracted hemipenes, Dowling and Savage (1960) published an influential paper showing a sampling of the extraordinary diversity among everted organs.

Although Dowling and Savage (1960:21) recognized that the majority of characters evident in everted hemipenes can in fact be recovered by dissection of the retracted organ, they stated (p. 22) that "everted preparations are much to be preferred." Indeed, today's workers generally prefer to use everted hemipenes in systematic studies, owing both to increased availability of field-everted organs and to development of techniques for manually everting retracted organs of museum specimens. However, eversion may bring about marked changes in relative positioning of various structures (Dowling and Savage 1960:20; Myers 1974:33); *Psomophis* (see above) provides an example in which there is not a precise correspondence between the apices of the retracted and everted organs. But, in some sense, everted organs seem easier to understand, and everted hemipenes obviously provide the best comprehension of their *potential* for expansion (whether or not maximal inflation is ever attained in the female's cloaca).

It needs to be emphasized in passing that better understanding is gained when retracted and everted hemipenes are compared. Complementary comparisons of retracted and everted hemipenes provide fuller comprehension and in some cases increase the number of taxonomically useful characters (Myers 1974:30–33; Myers

and Cadle 1994:13). Examples: Weak bilobation evident in a retracted hemipenis may disappear completely on eversion; similarly, a clearly non-bilobate hemipenis may reveal in the retracted state the retention of a weakly divided retractor muscle (such conditions can unambiguously establish character polarity within such a genus as *Trimetopon* [Myers, unpubl.]). A narrow gap between spines on the asulcate side of retracted organs expands in some species, but not others, to a diagnostically broad interspinal nude area on the everted organ (Myers and Cadle 1994:ftnote 7). The asulcate side of the capitulum may produce species-diagnostic folding in the retracted state (Myers 1974:31, Fig. 4). These few examples suffice to show that the retracted hemipenis should not be ignored as a potentially important source of taxonomic data.

Regarding the process of everting hemipenes of freshly killed snakes, Dowling and Savage (1960:17) wrote that "Since the hemipenis . . . is relatively easy to ready for study, the belief that it is difficult to locate or prepare is fallacious." Having seemingly changed his mind, Dowling (2002:13) now believes that "the proper preparation of everted hemipenes is a difficult process that requires some experience and skill"! We agree only that experience helps and we hope to provide a few useful tips in the following paragraphs.

Field (Fresh) Eversions.—Early field workers often did not fully evert hemipenes, or, even if they did, contraction of the retractor muscle frequently caused the organs to partially retract. Tying off the base of the everted hemipenis with thread and then opening the underside of the tail base medially (between the hemipenes) and severing the retractor muscle(s) might be all that is needed to provide a quick, simple, and useful field preparation. However, tying off the organ does not seem critical to maintaining eversion in many hemipenes if care has been taken to let the retractor muscle become relaxed so that it is no longer capable of contraction (see below); even then, the retractor muscle may be severed as a precaution. If the everted organ is to be tied off, we now realize that an easily removable overhand knot is preferable, because the thread may obscure or distort such important structures as basal spines or nude pockets (*fide* Cadle and Myers 2003:ftnote 7).

Some published instructions for everting hemipenes seem most applicable to large and moderate-sized snakes being preserved on a laboratory table (e.g., Dowling and Savage 1960; Branch and Wade "1976" [1977]). Dowling and Savage (1960:22) suggested that one should "slit open the ventral surface of the tail, cut the *m. retractor penis magnus* and inject fluid into the blood sinus at the base of the hemipenis so as to cause eversion." Few workers comprehend the last nicety, which is difficult and impractical especially when preserving small snakes in a temporary field camp in poor light, with the distracting drone of diurnal mosquitoes in one's ears. Usually it suffices to inject the tail base and effect eversion prior to slitting the tail and severing the retractor muscle; eversion is accomplished simply by fluid pressure within the tail. If the eversion proves difficult (probably because time was not allowed for the retractor muscle to relax), the tail can be slit medially and the retractor cut before continuing. A scalpel or razor blade may be used, but we prefer the convenience of fine-pointed dissecting scissors. It might be helpful to first start the eversion with external pressure on the tail base, by pushing forward toward the cloaca. With care, it is possible and sometimes desirable to leave one of the two hemipenes uneverted for later study in the retracted condition.

It is very useful and sometimes critically important for the muscles of the freshly-killed snake to become completely relaxed before injecting the tail base. (Not waiting for this accounted for most of our early failures to obtain complete field eversions of complex organs.) In order not to burst a small hemipenis nearing maximum inflation, a jeweler's loupe may be used to monitor the everting apex—in which case it is advisable to protect one's eyes by filling the syringe with water, which also will lessen skin exposure to formalin. In fact, *we suggest the routine use of water for hemipenial eversion*. The initial use of water seems not to affect the subsequent formalin-fixation of delicate hemipenial tissue and may also minimize retraction or shrinkage of the retractor muscle.

In the case of snakes having bilobed hemipenes, including especially those with slender apical structures (as in some *Micrurus* and *Enulius*), it becomes particularly important that the retractor muscles be allowed to become *completely* relaxed after injection of diluted sodium pentobarbital (Nembutal) or other killing agent. Myers (1974:31) recommended waiting the better part of an hour before everting hemipenes of rare snakes, and Branch and Wade ("1976" [1977]:550) extended the wait to 1–2 h, which is even safer if field time permits; placing specimens, especially small ones, in a jar or plastic bag with some water or damp paper towels will prevent desiccation during the wait.

Dowling (2002:13) recommended that the tail first be opened and that the retractor muscle be severed between the end of the hemipenis and its point of division, so that the divided retractor will not form a loop and "impede the complete eversion of the lobes, thus giving them a false appearance." However, separating the two slips of retractor muscle on a bilobed hemipenis normally is essential only when everting a retracted hemipenis from a museum specimen (see below). We find Dowling's suggestion impractical under field conditions because (1) we usually complete the eversion before cutting open the tail, (2) we do not always know in advance if a given snake has a divided hemipenis, and (3) the insertion and division of the retractor muscle is sometimes not evident except under a dissecting microscope. The retractor "loop" seemingly does not impede hemipenial eversion by the snake itself, nor need it do so now *if the retractor is completely relaxed* and severed farther back after eversion. Once the retractor is cut and the organ tied (if necessary) around the base, any subsequent shrinkage of the retractor is too minimal to cause noticeable distortion.

Everted hemipenes may be left on the snake, to be later removed if necessary for detailed study and illustration. The organ will often deflate, in which case remaining air or fluid may be pressed out and the organ re-inflated at any time with colored petroleum jelly (see below); other substances that have been successfully used include paraffin (Ortenburger 1923), liquid latex (Dowling and Savage 1960:22), and agar (Manzani and Abe 1988); everted organs may also be dried (Manzani and Abe 1988), although we question the practicality of this for small delicate structures. If the everted (*or* retracted) hemipenis is to be cut away from the snake, care must be taken to excise the organ at its very base so that proportions are not affected.

What to do with hemipenes only partially protruded at the time of field preservation? These were generally considered as irrecoverable, but that is no longer so. Myers (1974:30) noted that "if

only the base is everted, the tail can be opened and the organ pulled back and studied in the retracted position." For organs partially everted beyond the base, Myers adapted circa 1967 a hot-paraffin technique for rescuing partially everted organs of small dipsadine and xenodontine snakes; Myers (1974:30) speculated that the intense heat of the paraffin softened preserved tissue that would only burst under pressure from other liquids. Branch (1986:287) found Myers' technique to be "rarely successful" for organs that were less than two-thirds everted. However, partial eversions can now be approached using methods that were subsequently developed for everting fully retracted hemipenes of preserved specimens. In fact, as pointed out by Zaher and Prudente (2003), it may be easier to evert a hemipenis that was preserved partially everted than one that is completely retracted (see following).

Laboratory Eversions from Preserved Specimens.—Dowling (2002:13) stated that "with considerable effort, it is possible to evert the hemipenes to some degree from museum material (Pesantes 1994)." In fact, however, eversions of preserved, retracted hemipenes require only a little learning and patience, and some (not all) can not be distinguished from fresh eversions.

It has never been pointed out, but should be acknowledged, that Dowling's own research program sponsored the development of such techniques some 30 years ago. At the time (1968–1973), Frances L. Gibson (née Waite) was working in the capacity of artist-technician for Dowling, who was then a Research Associate at the American Museum of Natural History. She was versed in snake anatomy (e.g., Gibson 1966, 1970) and a talented illustrator, being responsible for the outstanding plates and line drawings in Dowling and Savage (1960). With advice and support from Dowling, Waite Gibson realized that invaginated organs of museum specimens might be everted if the tissues could be softened and returned to an elastic state. A method of softening was partially described by Gibson (1970) and her "improved and completely different technique for everting hemipenes of preserved specimens" was mentioned by Myers (1974:30), who adopted the essentials of it for occasional use starting in the 1970s. Gibson (1970) made reference to a manuscript and in 1974 gave a draft copy to Myers; she unfortunately never published the complete description, but gave permission to quote it (letter from Waite Gibson to Myers, 12 August 1986).

The softening in the Waite Gibson Technique involved, as originally stated, a "soaking in glycerine, and then in a solution of trisodium phosphate and 'Calgonite'" (Gibson 1970). Trisodium phosphate (Na_3PO_4) is a detergent that had been shown useful for softening and rehydrating dried animal tissue (Van Cleave and Ross 1947a, b); Calgonite is the trade name of a water softener containing sodium phosphates and sodium carbonate.

For initial softening, Waite Gibson (MS.) opened the tails and placed *entire* small and medium-sized snakes in undiluted glycerine for up to 6–8 days, followed by two days in a saturated solution of the two detergents. (Myers later found that just removing the hemipenis from the snake directly to a saturated solution of Na_3PO_4 worked about as well.) Waite Gibson described the eversion process as follows:

> The tail is split and the retractor muscle cut as described (Dowling and Savage, 1960, p. 21; and Myers, 1972, pp. 61–63 [= draft of 1974:31]). If the organ is bilobed, the retractor muscle must be cut fairly close to the lobes, anterior to the point where the two fascicles of the muscle coalesce. The preserved muscle, even though softened, is not flexible enough to permit the two lobes to fully evert while still interconnected. Next the hemipenis is freed from its sheath, beginning at the retractor muscle and working forward. The hemipenis is left attached at its base. With blunt forceps, the hemipenis is gently pushed forward as it would normally evert. The forceps should have well-worn teeth as the tissues are easily torn, especially on very spiny specimens. When about a quarter of an inch is everted, it is possible to inject some petroleum jelly into the sinus. This is done with a syringe (a 5 cc syringe with a No. 18 needle for medium sized snakes and a No. 22 needle or a 2 cc disposable syringe for smaller snakes) and petroleum jelly mixed with carmine dye. Sometimes the jelly flows more easily if the filled syringe is allowed to stand a few minutes in warm water. The needle of the syringe is inserted into the sinus of the hemipenis by slipping it forward between the walls of the inverted and everted portions. Care must be taken to keep from puncturing the walls. The jelly thus injected facilitates further eversion, which is continued by alternately pushing the hemipenis forward with forceps and pressing the jelly forward with the fingers, adding more jelly as needed. In bilobed specimens, a dull probe may be used to make certain the lobes are everted to their fullest extent.
>
> When the hemipenis is fully everted, or nearly so, it may be removed from the snake and inflated [with] more petroleum jelly. A better specimen is obtained if the needle can be inserted into the lymph sinus and this inflated also. Since the tissue is so thin, this is sometimes difficult to do without puncturing the outer wall. Preserved specimens can not be expanded to the same degree as fresh specimens so that there is a disparity in diameter between the two. (Waite Gibson, MS.)

Because it was unpublished, Waite Gibson's method was little used by other workers. Her drawings of hemipenes, including an unknown number of organs prepared by this method, are frequently seen in Dowling's publications. If any of his published figures shows a fully everted hemipenis that appears less robust or less bulbous than a new organ being compared, it may be that the drawing represents one of Waite Gibson's early preparations from museum specimens.

Pesantes (1994) subsequently published another method of preparing hemipenes from preserved snakes. He initially removed the organ from the snake and softened it for three days in a 2% solution of potassium hydroxide (KOH). After testing for flexibility, washing, and buffering the remaining hydroxide, the hemipenis could be everted with round-tipped forceps. Pesantes gave little detail of his eversion process beyond mentioning that each lobe of a bilobed organ should be everted separately. After eversion, Pesantes recommended preparing the hemipenis for wet or dry preservation following the methods of Manzani and Abe (1988). His one illustration, a photograph (Pesantes 1994:Fig. 1), showed side-by-side views of two *Bothrops moojeni* hemipenes filled with agar solution; the one prepared from a preserved snake appears virtually identical with one from a freshly killed specimen. Pesantes' demonstration that KOH provides a convenient and effective softening agent was a significant advance. Many of the organs illustrated in Zaher (1999) were prepared using a modification of Pesantes' technique.

We currently use a combination of the Pesantes and Waite Gibson techniques, with modifications of each. KOH probably is a better softening agent than Na_3PO_4 (comparisons would be useful), but

three days immersion in 2% KOH probably is too long for small delicate organs. Zaher (1999:7) increased the solution to 3% but greatly decreased the soaking time. There is concern that buffering with hydrochloric acid as recommended by Pesantes might damage mineralized spines and spinules in small organs (Cadle 1996a:372). It seems sufficient to stop the action of KOH by flooding the softened organ in a large volume of water and several changes of alcohol.

We now use a 2% or 3% KOH solution and follow Zaher (1999:7) in immersing the isolated hemipenis "either for 1–6 hours or overnight," or even longer depending on size and condition of preservation and other factors (e.g., very spiny organs being more difficult than smooth ones). Because of scheduling problems, we have sometimes alternated difficult hemipenes between KOH and diluted glycerine or 65% alcohol over a period of several days (the KOH time for each round being up to several hours). The organ is inspected under a dissecting microscope between soakings, until flexibility seems maximal without totally breaking down the tissues.

When the organ is flexible enough, the base can be rolled back cufflike (e.g., by pushing against opposite sides of the open base with parallel ends of forceps). Because of the narrowness of the base, it usually is necessary to first cut a short slit in the base on the side opposite the sulcus spermaticus (usually located in a thick ridge of tissue on one side); a cut on the sulcate side may spread up the sulcus spermaticus, resulting in the opening of a long split (Zaher and Prudente 2003). Holding the extreme base with forceps, one starts to evert the base by pushing it forward with a second pair of smooth, blunt-tipped forceps. This is usually the most tedious part of the process, and a lack of flexibility may indicate the need for further soaking in KOH. In this way the entire organ can be gradually everted; a rounded-end narrow probe of metal or polished wood may be helpful, particularly in bilobed organs (the round heads of no. 5 or no. 7 insect pins work well in the lobes of small hemipenes). The manually everted organ can now be inflated with petroleum jelly, which may also help in the final everting of small apical structures and narrow lobes.

Yuki (1997) claimed without elaboration that a semi-everted hemipenis "will not produce a general shape similar to that of organs that are completely everted, as the action of the KOH solution is not uniform." This has been neither our usual experience nor that of Zaher and Prudente (2003), although injecting KOH into the lumen of the hemipenis and increasing total immersion time might be needed in some cases. After being sufficiently softened and relaxed, partially everted but undamaged hemipenes should be more easily eversible than fully retracted ones, since the beginning of the process already has been done. If a bilobed organ already has been mostly everted, it can be grasped between the fingers and the retractor muscle pulled back far enough to sever the two slips of muscle anterior to their merging. In the case of single or very weakly bilobate hemipenes, it should be sufficient to snip the retractor shorter so that it disappears into the organ being everted.

In line with Waite Gibson's early observation (see above), we emphasize that lab-everted hemipenes softened either in Na_3PO_4 or KOH may be fully everted without always becoming maximally expanded (inflated), in which case they are of a smaller diameter than field-everted organs. Whether a longer period of softening would have returned more elasticity to the organ usually is not clear. Taxonomic usefulness is not necessarily hindered because all structures are revealed, but taxonomic inference should not be made by comparing widths or circumferences of lab-everted hemipenes with fresh eversions made at the time of preservation. We have not rejected the possibility that lab-everted organs might be overextended longitudinally even while resisting expansion to "normal" diameter, but reliable observation or histological evidence is lacking. At the moment, we consider that lab-everted and freshly everted organs can be compared when assessing relative lobe length (but not width) as a species character (e.g., in the *Geophis brachycephalus* complex; Myers 2003).

Waite Gibson discovered in the late 1960s the practicality of using petroleum jelly for subsequent inflation of field-everted hemipenes and for helping to evert retracted organs of museum specimens. We cannot overemphasize the usefulness of this readily and widely available substance. It can be drawn into a hypodermic syringe (with needle removed) with little prior warming; several syringes can be filled and left on the workbench indefinitely until needed, and used at normal room temperature. For ease of flow, the needle should be sized to the syringe (e.g., a 26- or 20-gauge needle on a 1-cc or 2-cc syringe for small hemipenes, a 16-gauge needle on a 10-cc or 20-cc syringe for larger ones). Branch and Wade ("1976" [1977]:551) thought it advisable to immerse the hemipenis in warm water in order to "prevent blockage of the needle by cooling petroleum jelly," but this is a procedure that had been suggested for paraffin injection (Myers 1974:30) and is not a concern for petroleum jelly. The syringe itself can be placed in hot water for a few minutes if faster flow is desired, but this is not essential and it sometimes seems easier to monitor and avoid bursting small hemipenes that are being slowly inflated. The tip of the needle should *always* be filed blunt before use.

If the hemipenis resists eversion, the petroleum jelly can be squeezed out and the organ put back into KOH. Leakage of jelly from small tears will soon stop when the organ is plunged into water or alcohol, and excess jelly is easily lifted or scraped from the surface of the organ with a teasing needle or fine forceps. One or more large jars of inexpensive petroleum jelly can be pigmented and stored indefinitely.

Petroleum jelly should be colored prior to use in order to enhance surface ornamentation of the hemipenis, thus greatly facilitating study and illustration. Carmine dye was used by Waite Gibson and subsequently by Myers and others. However, if carmine-dyed petroleum jelly is not first vacuum-strained prior to use, solid particles of carmine might plug narrow-gauge hypodermic needles at awkward moments. Zaher found while working at the American Museum that red candle-wax coloring made an effective substitute for carmine dye.

We urge anyone wishing to use these techniques to experiment with some common snakes before working with specimens of rare species, and to remember that small organs tend to be more delicate and easily damaged than large ones. Damaged organs sometimes can be repaired with cyanoacrylate glue before filling with petroleum jelly (Zaher 1999:8). Although occasional organs cannot be everted completely, they may still show useful details of structure and microornamentation and may still be worth illustrating if other material is not available—but the incompleteness or probable incompleteness of the eversion should be noted, as rec-

ognized by Dowling (2002) who attempted to identify some incompletely everted hemipenes illustrated in the literature.

An apical depression or dimpled tip is "almost always an indication of incomplete eversion" of snake and lizard hemipenes (Myers and Donnelly 2001:49). There are a few exceptions to this working generalization, as in some species of the Madagascan genus *Liopholidophis*; the four species comprising the *stumpffi* group are characterized by an "umbelliform" depression at the tips of the lobes, which is correlated with a "broad internal attachment of the [retractor] to the somewhat pleated tissue at the tips of the lobes" (Cadle 1996b:441, Figs. 34–36). Dowling and Duellman ("1974–1978" [1978]:Fig. 112b.5) show the hemipenis of *L. lateralis* as lacking such a depression, but it is an interpretive drawing based on the assumption of incomplete eversion; the actual organ (AMNH 60691), on which the drawing is based, has the branches of the sulcus spermaticus entering an apical depression. This hemipenis, everted by Waite Gibson from a museum specimen, is much narrower and much less robust than a field-everted organ of the same species (cf. Cadle, 1996b:439, Fig. 35).

An apical depression similar to that of the *Liopholidophis stumpffi* group also is present on the non-bilobed hemipenis of *Elaphe longissima*. According to Schultz (1996:23, Fig.27), this depression is part of the normal morphology and not the result of incomplete eversion as previously thought.

Although some of the techniques discussed above (e.g., eversion and use of colored petroleum jelly) are applicable to lizards, we have worked with the hemipenes of relatively few groups of lizards and have little to contribute in a general sense. Böhme (1988) and Ziegler and Böhme (1997) presented extensive reviews of lizard hemipenes, and Savage (1997) commented on parallelism and divergence in some terminology used for hemipenes of male snakes and lizards. The "diverticulum" (Arnold 1984) or "hemiclitoris" (Böhme 1995; Ziegler and Böhme 1996) of female lizards is a hemipenial homologue—a rudimentary hemipenis—also known from a few scattered reports for female snakes (e.g., Hoge et al. 1959; MacLean 1968; Hardy 1975; Ziegler and Böhme 1997:30).

The available literature seems to suggest that in female snakes a recognizable hemipenial homologue or parts thereof (e.g., muscles only) varies from commonly or usually absent to variably present within genera and species, presumably because of the juxtaposition of unknown hormonal and/or developmental events, and complicated by interpretations of intersexuality. The mammalian clitoris (a penile homologue normally always present, with its own function and species-specific morphology) does not seem to be an appropriate analogy in light of such variation, and at this time we personally prefer not to use a special term for female hemipenes. Although much more attention needs to be given to snakes, female hemipenes (sometimes eversible) and their associated musculature are known to be taxonomically widespread among lizards (Arnold 1984; Ziegler and Böhme 1997).

Dowling (2002) recently suggested that the hemipenial pattern of *Siphlophis* described by Zaher and Prudente (1999) as the T-shaped condition is actually an artifact of preparation because of incomplete eversion. Dowling also argued that hemipenial preparations of *Conophis vittatus* and *Hydrops martii* figured by Zaher (1999: Figs. 41 and 52, respectively) show similar eversion deficiencies.

Despite the convincing visual effect produced by his figure 1, a more careful examination of the arguments and examples used by Dowling shows that his criticisms are founded upon two fallacious ideas: 1) that science is a matter of authoritative knowledge instead of a search for answers by empirical observation and test of hypotheses; and 2) that hemipenial morphology shows some special value as a source of information at the detriment of other morphological complexes.

We do agree with Dowling (2002) that hemipenial features are informative at most taxonomic levels within snakes. However, we do not view hemipenial morphology as more reliable than any other morphological complex, as advocated by Dowling who believes that hemipenial structures are less influenced by ecological and behavioral constraints. As shown by Zaher (1999), hemipenial features are surprisingly variable at all taxonomic levels within colubroids. The tribe Pseudoboini (*sensu* Zaher 1999) is an excellent example of a moderately speciose group of colubrid snakes with a highly variable hemipenial morphology (Zaher 1994). Additionally, a number of hemipenial features have been reported to appear homoplastically in several unrelated taxa within the New World xenodontine and dipsadine radiations (Zaher 1999; Zaher and Caramaschi 1994). A nude area associated with the tip of the lobes appeared independently in the Xenodontini (as an apical disk) and *Oxyrhopus* (Zaher and Caramaschi 1994). Unilobation was derived independently several times (e.g., within *Apostolepis*, *Arrhyton*, *Contia*, *Echinanthera*, *Nothopsis*, *Taeniophallus*, and *Xenopholis*). Reduction or loss of calycular walls to form flounces may have arisen independently in *Arrhyton*, *Conophis*, *Farancia*, *Helicops*, *Hydrops*, *Ialtris*, the Xenodontini, and within the Tachymenini. Highly complex transformation series as well as homoplastic occurrences of hemipenial structures at low taxonomic levels do not support the hypothesis of hemipenes being inherently stable morphological complexes (Zaher 1999; Zaher and Prudente 1999).

In order to support our previous observations, we analyzed additional hemipenial material from the Instituto Butantan, totaling seven specimens with previously everted organs (2 *Siphlophis pulcher*, 3 *S. longicaudatus*, and 2 *S. compressus*). Although some of them are only partially everted, all present a clearly T-shaped condition. We completed the preparation of three hemipenes (one from each species) and photographed the most important steps of the procedure. Figure 1 shows these steps on a hemipenis of *S. longicaudatus* (IB uncatalogued). This preparation confirms that the "T-shaped" condition is not an artifact of preparation.

Dowling failed to test accurately our results (Zaher and Prudente 1999) with additional hemipenial preparations of the genus *Siphlophis* (including *Tripanurgos*). His Figure 1 does not represent empirical results based on new preparations, but the author's belief of what might have occurred with our preparations. Dowling attempts to justify his perspective by mentioning his long experience with hemipenial morphology: "I must admit that it took me many years to recognize these problems…." In that sense, his contribution is unscientific and misleading.

Dowling supports his point of view with a montage in which Zaher and Prudente's (1999) original figures of T- and Y-shaped hemipenes are used as background to illustrate the retractor muscle position as a possible cause of the artifactual preparation (Dowling 2002: Fig. 1). It is important to stress that Dowling did not examine the original material used by Zaher and Prudente (1999). As such, his Figure 1 is merely a hypothetical reconstruction of what Dowling believes would be the position of an unsectioned retractor muscle in the hemipenes prepared by Zaher and Prudente (1999). The retractor muscle restricted by ties at the basal end of the T-shaped hemipenis is also another extrapolative deduction (Dowling 2002: Fig. 1B, lower right).

Dowling suggested that failure to section the retractor muscle

caused the hemipenis of *Siphlophis* to retain a T-shaped condition: "if this element of the procedure is neglected (cutting the retractor muscle too far posterior – or not cutting at all) the divided retractor muscle will form a loop in the 'lobular crotch' between the two lobes of the hemipenis" (Dowling 2002:13). However, Dowling figured the Y-shaped hemipenis with an unsectioned retractor muscle (Dowling 2002: Fig. 1). Such inconsistency exposes the speculative ground on which Dowling built his arguments. Indeed, it is not clear from his discussion if the T-shaped condition is an artifact because of an uncut retractor muscle or to a muscle restricted by ties at the base of the organ. According to Dowling (2002:13), "the T-shaped figures shown by Zaher and Prudente also demonstrate the distortions caused by an additional problem.... The short and convoluted hemipenial body and the distortion of the sulcus spermaticus in the T-shaped figures are clear indications that the retractor muscle was included in and restricted by the tied base." However, a quick examination of the original material prepared by Zaher and Prudente (1999) would have saved misleading speculations as it confirms that the muscle has been sectioned and the two remaining tips of each branch are not tied at the base of the T-shaped hemipenis but lodged within their respective lobes. Clear examples of restricted or uncut muscles never result in a T-shaped hemipenis with *fully everted* lobes, as is the case in *Siphlophis*, but rather will result in organs with partially everted lobes. Although Dowling (2002:13) acknowledged this point by arguing that the failure to cut the retractor muscle will "impede the complete eversion of the lobes, thus giving them a false appearance," he failed to observe that the hemipenes figured by Zaher and Prudente (1999) have fully everted lobes.

Myers and Cadle (2003) proposed to distinguish two very different conditions of hemipenial preparation: 1) a "fully everted" hemipenis, and 2) a "maximally expanded" (or inflated) hemipenis. According to Myers (pers. comm.), maximally expanded hemipenes are always fully everted, but fully everted ones may not be maximally expanded. Such distinction is very helpful because it highlights an important variable for a proper interpretation of hemipenial features, as we will discuss in more detail below.

Dowling (2002) suggested that partially everted organs should not be used as source of information. As shown by Zaher (1999), partially everted organs may be of great value for supraspecific comparisons as they may show systematically informative details of structure and micro-ornamentation on the parts of the organ that are adequately everted. Also, incompletely everted field-prepared hemipenes can be easily prepared again, resulting in fully everted, "maximally expanded" organs (see Myers and Cadle 2003; *contra* Dowling 2002). The hemipenial preparation shown in Figure 1 illustrates adequately this point.

Differences in shape and form because of artifactual preparations might be classed in three distinct categories: 1) incomplete eversion of the lobes; 2) incomplete inflation or expansion of the hemipenial body and lobes; 3) "distorted" or strongly recurved hemipenial body and/or lobes due to preservation procedures or unsevered retractor muscles.

Partially everted hemipenes that fall in Category 1 above are easily diagnosed as such by the characteristic depression observable on the tip of their lobes. A fully everted organ is characterized by totally everted lobes, with tips showing no invaginated or depressed tissue (except in *Liopholidophis*; see Cadle 1996; Myers and Cadle 2003). Hemipenes with pointed or rounded tips can be considered, without hesitation, to be fully everted. The terminus of the sulcus spermaticus visible on the rounded surface of the lobe is another indication of a fully everted organ. However, this last feature may not be applicable on hemipenes with large apical disks or nude areas on the tip of the lobes because the sulcus tends to terminate on the edge of these structures.

A fully everted hemipenis might be either only partially or maximally expanded. "Deformations" that fall in Category 2, i.e., fully everted hemipenes that are only partially expanded, in general, have a direct effect on the overall shape of a hemipenis without affecting significantly the microornamentational pattern of the surface. Besides incomplete filling of the organ, destructive steps of the procedure, such as splitting of the organ base for eversion or accidental perforations during injection of petroleum jelly (see below), may also lead to partially expanded organs.

As clearly explained by Myers and Cadle (2003) "a maximally expanded hemipenis has inflated to the fullest extent allowed by its original elasticity... As with a balloon, there are imperceptible degrees of inflation, resulting mainly in a changing circumference." Freshly prepared hemipenes are likely to expand to their greatest elasticity whereas organs dissected out from museum specimens might not expand always to their fullest original extent. The degree of extension of a preserved hemipenis is highly variable and might cause slight differences of proportion when hemipenial preparations from several preserved specimens are compared. However, based on previous results obtained from examination of large series of hemipenial preparations (Myers 1974; Zaher 1999), such differences have little or no impact on systematic data. A common variation in micro ornamentation is illustrated by the differential degree of "erection" of spines. A partially expanded organ typically shows rows of spines (when present) in a "resting" position, more or less parallel to the hemipenial wall, whereas maximally expanded organs will show erected spines with stretched tissues at their base. Dowling seems to recognize only maximally expanded hemipenial preparations as valid for descriptive and comparative studies (although he never made clear such distinction), rejecting any observation made on fully everted organs that would not show a maximally expanded condition.

Dowling also rejects observational data on hemipenial preparations with "distorted" (= strongly recurved) shapes. We here use Dowling's word "distortion" only with caution since the word is inappropriate to describe the hemipenial condition in question. The "distorted" condition suggested by Dowling actually refers to a perfectly everted and inflated organ of *Psomophis genimaculatus* (Myers and Cadle 1994). The so-called "distortion" shown by the *Psomophis* hemipenis clearly corresponds to a strong curvature of the hemipenial body with virtually no consequence to the micro ornamental pattern, a typical case belonging to Category 3. Totally everted, maximally expanded hemipenes may often show a strongly recurved shape, as shown by the hemipenes of *Psomophis genimaculatus* (figured in a straight position by Myers and Cadle 2003), *Taeniophallus occipitalis* (Zaher 1999: Fig 92), *Tomodon dorsatus* (Zaher 1999: Fig 91), or *Antillophis parvifrons* (Zaher 1999: Fig 31). As in the examples of *Psomophis* (Myers and Cadle 2003) and *Antillophis* (Zaher 1999), a "distorted" (= strongly recurved) hemipenis can be straightened to a nearly straight posi-

tion with the aid of pins without changing the micro-ornamentation pattern. Indeed, "distortions" of that nature do not affect at all the micro-ornamentations on the surface of the hemipenes. Dowling wrongly concluded that the *Psomophis* hemipenis figured by Myers and Cadle (1994) was so badly distorted that it would not be useful for drawing systematic conclusions. The exact reasons that lead to hemipenial shape distortions (= strong curvatures) are still unclear. It might be caused by inappropriate preservation procedures (Category 3 defined above) such as unrelaxed and unsevered retractor muscles (Myers and Cadle 2003), or inadequate positioning of the specimen at the time of preservation resulting in excessive curvature of the tail.

Although we recognize the importance of having maximally expanded, minimally "distorted" preparations, we regard "distorted" hemipenes as important material that is interpretable and useful for systematic purposes. This broader approach leads us to view preserved specimens of museum collections as an invaluable source of hemipenial information, although personal experiences have shown that hemipenes from preserved specimens often present problems (Categories 2 and 3).

Hemipenial preparations on freshly-killed specimens.—Hemipenes are easier to prepare from freshly killed specimens than from museum specimens. In the field, the procedure can be straightforward: formalin is injected into the ventral surface of the tail of the freshly killed specimen until the hemipenis is everted by fluid pressure. The needle should puncture at a level that could not inflict damage to the hemipenis. However, such simple technique often results in partially everted organs although it should not be viewed as a problem since partially everted organs (via formalin injection) can be subsequently dissected out and prepared in the lab. Partially everted organs do greatly simplify the process of complete eversion in the lab (see below). A more efficient, but time consuming procedure, involves dissection of the tail and retractor muscles. It has, however, the disadvantage of being impractical to apply on small specimens in the field without a dissecting scope, which restricts the use of this procedure to the lab. The procedure is as follows: 1) slit open the ventral surface of the tail on its midline; 2) cut the retractor muscle just posterior to the tip of the lobe(s) so as to leave the smallest possible piece of muscle attached to the lobe (a careful examination of the tissue color and texture is essential to define the exact location of the tip of the lobes, see below); 3) when the hemipenis is bilobed, gently separate the lobes from each other and remove with caution the sheath of tissue around the hemipenis from the tip to the base; 4) force the hemipenis with thin, rounded tweezers toward the base of the organ, causing its eversion (note that the hemipenis is attached to the specimen; final eversion of the tip of the lobes can be done manually by finger pressure); 5) inject formalin inside the everted hemipenes through the hole at the base of the organ and force it to fully expand (we do not recommend tying off the base with a strand). This procedure permits field or laboratory preservation of hemipenes in a maximally expanded position, which can be later removed from the specimen and filled with petroleum jelly.

An important suggestion to field collectors who are not willing to prepare hemipenes in the field would be to avoid puncturing the area of the tail where the hemipenes are lodged during the process of fixation. Formalin can be injected in the dorsolateral region of the tail or gently injected along the ventral midline of the tail. Simple procedures of fixation, as the ones described above, can greatly augment the chances of subsequent preparation. An illustration of the possibilities provided by good preservation conditions is given by some of the maximally expanded hemipenial preparations obtained from rare specimens that were fixed and stored at the Paris Museum at the end of the 19th Century (Zaher 1999).

In order to clarify some of the more specific steps and provide a guideline for preparation of hemipenes from museum specimens, we furnish a detailed description of our procedure below, based on the steps illustrated in Figure 1.

Hemipenial preparations on museum specimens.—Hemipenes can be prepared from museum specimens that have either totally inverted organs or partially everted ones. The procedure figured herein was performed on a partially everted organ. Partially everted hemipenes are significantly easier to fully evert and prepare than totally inverted ones because the most difficult and delicate step of the process consists of forcing the inverted base of the organ to evert. This is generally done with the help of rounded forceps that serve to secure firmly the basal region of the organ while the rest of the organ is forced manually toward the forceps, thus causing the base to evert. However, the base of the organ is often tighter than the body and lobes, which renders nearly impossible the eversion process without causing irreversible damage to the hemipenis. A solution to this problem consists in cutting longitudinally the basal region of the hemipenial body on its asulcate side (the incision cannot be done on the sulcate side because invariably the cut will spread to the sulcus spermaticus causing it to open and extend toward the lobes). Arrow 1 in Figure 1B shows the approximate length of a cut to be performed at the base of the asulcate side of a totally inverted organ for subsequent eversion. The hemipenis of *Alsophis anomalus* figured by Zaher (1999: Fig. 24) illustrates adequately this procedure.

Any hemipenial preparation from an inverted or everted organ should be done on hemipenes that have been previously removed from the specimen. There should be no attempt to evert or invert a fixed organ before soaking it in a solution of potassium hydroxide (KOH; see next steps below). The tail first has to be opened by an incision on its ventral midline (Fig. 1B). In the case of either an inverted or partially everted organ, the retractor muscle must be severed and removed from the tail as shown in Figure 1B (arrow 2). At this point, the retractor should be severed as far as possible from the hemipenis (Fig. 1B: arrow 2). The long strand of muscle will be helpful in the next steps for pulling back the lobes to an inverted position (see below). With the retractor tightly pressed to the hemipenis, the latter is removed from the specimen via a circular incision around the base of the organ, through the thin mucosa that forms the tissue of the cloacal region (Fig. 1C: arrow 3). This incision should promote the removal of the entire hemipenis along with its retractor muscle (Fig. 1C). After removal, the organ is immersed in a solution of 2% or 3% potassium hydroxide (KOH) for softening the tissues. We recommend injecting KOH with a rounded needle inside the hemipenis to help accelerate the process and to identify possible holes on the hemipenial wall. Softening tissues with KOH is an essential step that provides elasticity to the organ and reduces the friction between the tissue walls during the eversion procedure (Pesantes 1994). Time of immersion in KOH is variable but should not be more than a half a day (except

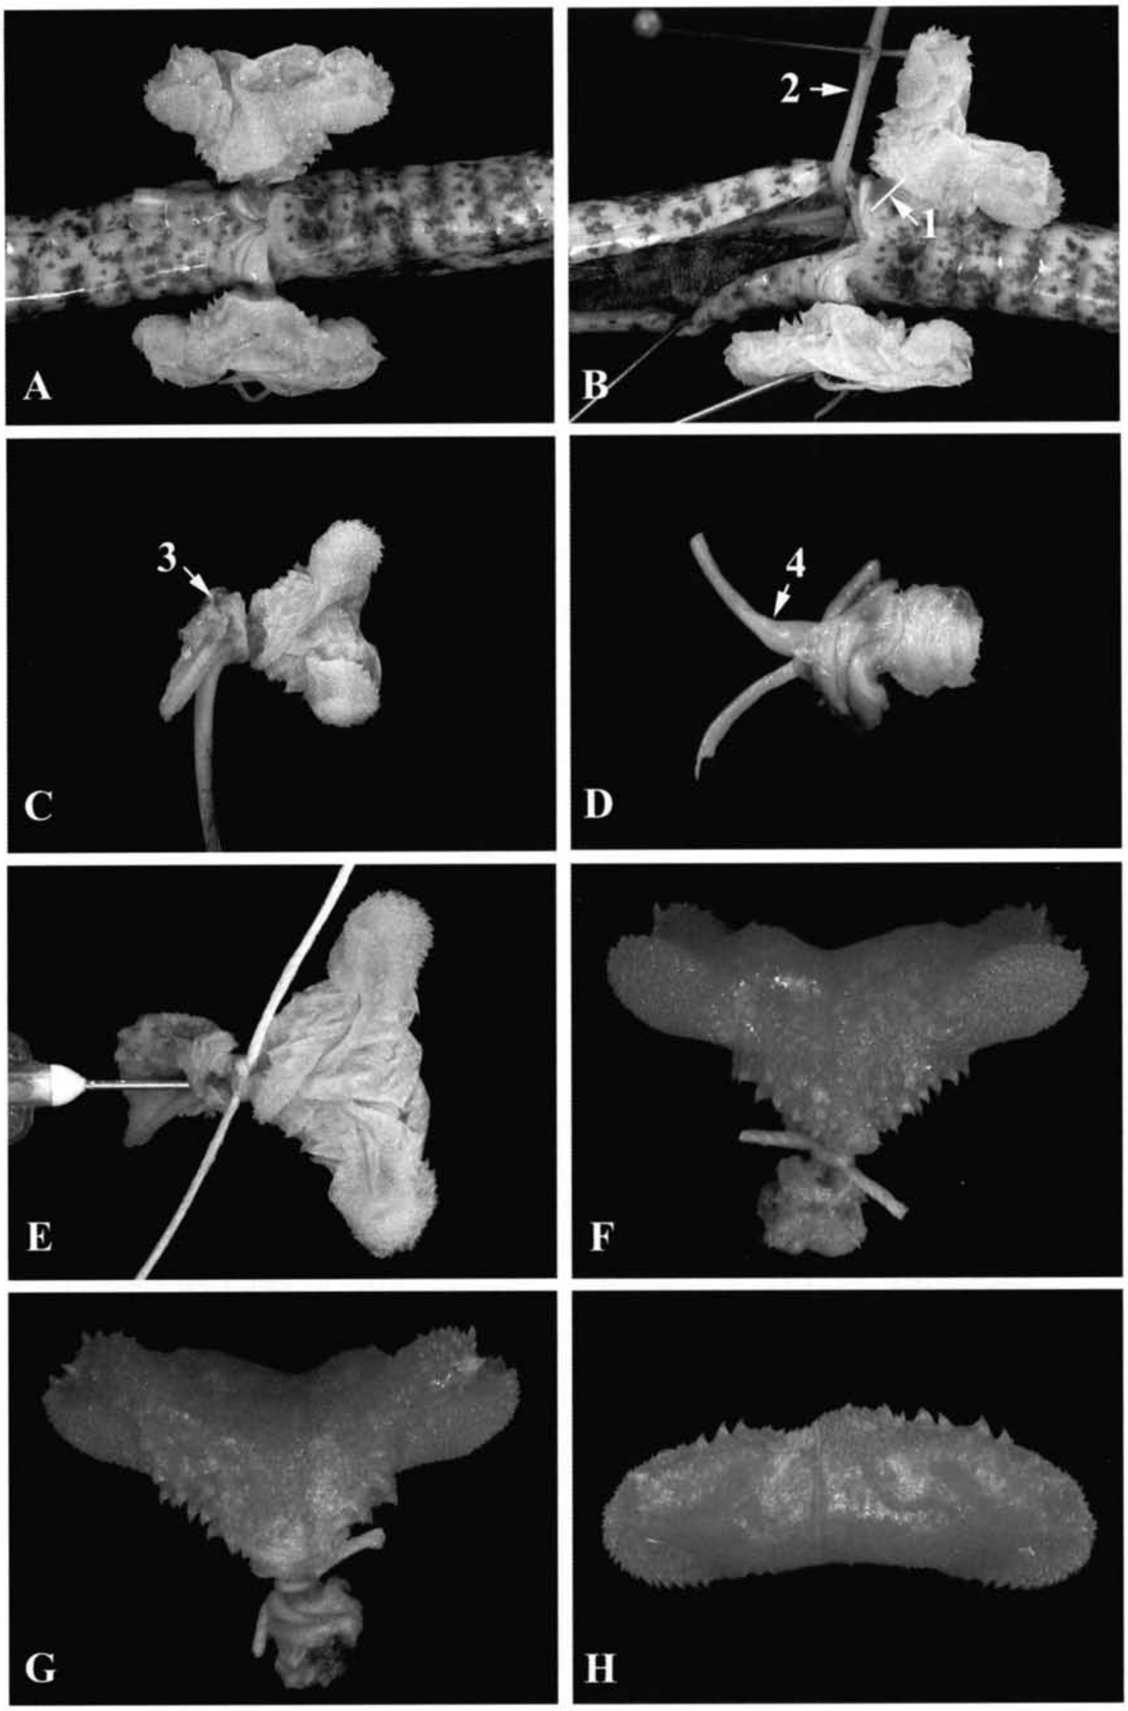

FIG. 1. Steps illustrating the eversion and filling with petroleum jelly of a partially everted hemipenis from a preserved specimen of *Siphlophis longicaudatus* (Instituto Butantan, uncatalogued). A: ventral view of the cloacal region prior to dissection. B: ventral surface of the tail cut and opened to expose retractor muscles. C: right hemipenis dissected out. D: right hemipenis partially re-inverted to expose the lobes. E: right hemipenis totally everted and tied around a needle. F, G, H: sulcate, asulcate and dorsal views (respectively) of the hemipenis, fully expanded and showing a T-shaped condition. See text for details.

for exceptionally large preparations that might stay overnight). Most of the hemipenial material prepared by us did not remain in 3% KOH for more than one hour. The hemipenis is ready for eversion when the tissue becomes rubbery. We recommend not rinsing the hemipenis until eversion is complete because KOH solution reduces friction during the process of eversion. Partially field-everted organs are better candidates for a complete and easy eversion because their basal portion is already on the correct, everted side. Bilobed organs that are half-way everted should be inverted again until the basal crotch appears on the inverted side. This can be done by pulling the organ back by the retractor muscles that were previously left long for this purpose. This procedure allows separating the lobes from each other and removing the thin sheath of tissue from around the hemipenis (Fig. 1D). After the latter procedure is concluded, the hemipenis is ready to be fully everted (Fig. 1E). However, before everting the hemipenis, the retractor muscles should be cut just posterior to the tip of their lobes. The exact location where the retractor muscle inserts on the tip of the lobe is generally marked by a slight constriction (see Fig. 1D: arrow 4). Differential color and texture between lobular and muscular tissues also help to define the precise location of the boundary.

Totally inverted organs are more difficult to evert. As mentioned above, a practical solution for everting totally inverted organs consists of slitting open the asulcate side of the base to force the eversion of the organ through a larger (basal) opening. This should be done using rounded forceps that will serve to grab the tissue proximal to the end of the slit and secure it firmly (avoiding the slit to enlarge) while, with the aid of other forceps or with the fingers, forcing the tissue of the base to roll over and evert toward the tweezers securing the base of the slit. As soon as the base is everted, the rest of the hemipenis can be forced toward it and fully everted. It is important to mention that the tissue of the lobular crotch and lobes is always thinner and much more fragile than the hemipenial body. Special care should be given when forcing these regions to evert (separate eversion of the lobes in bilobed hemipenes is not recommended; both lobes should be grabbed by the rounded forceps and forced together toward the base).

At this step in the procedure, pre-existing or accidental holes can be patched with cyanocrylate glue before filling the organ with agar or petroleum jelly. The area to be glued must be dried before applying the glue (remove alcohol by squeezing the area between your fingers with absorbent paper). It must be kept in mind that this procedure often does not allow perforated lobes to expand at all, and the rest of the organ to expand only to some degree. However, we find the resulting preparation useful since it often permits the assessment of a significant part of the hemipenial structures that might be of systematic value.

The everted organ is preferentially filled by injecting colored petroleum jelly through a syringe (Myers and Cadle 1994). Colored petroleum jelly is preferable because it enhances surface ornamentation (Myers and Cadle 1994). This can be done with Carmine Dye (Myers, pers. comm.) or with concentrated wax dye (candle dye). The syringe should be uniformly filled with petroleum jelly and the needles, with rounded tips, adjusted to the size of the organ to be filled. Petroleum jelly is easy to manipulate because it can be maintained in a liquid state in warm water, although some persons prefer to use it directly at normal room temperature, a procedure also allowed by the petroleum jelly (see Myers and Cadle 2003). We personally prefer to use warm, liquefied jelly because it helps distend the tissues of the hemipenis during injection. Warm and cold water should be kept nearby during the filling procedure and used eventually to liquefy the jelly inside the needle or to stop or diminish possible leaks (the syringe and needle, along with the mounted hemipenis, can be dropped directly into cold or warm water). For proper filling procedure, a totally everted hemipenis has to be tied to a rounded needle with a thread and all the air should be removed from the organ (Fig. 1E). Figures 1F, 1G, and 1H show the sulcate, asulcate, and dorsal views of a fully everted and expanded hemipenis of *S. longicaudatus* using the procedures described above. The result confirms that the T-shaped condition is not an artifact of preparation.

We agree with Dowling (2002) that incompleteness of eversion should always be noted. Zaher (1999) failed to furnish this information because he was focused on showing major hemipenial patterns within a large and diversified lineage of snakes. However, only four hemipenes prepared and figured by Zaher (1999) are not fully everted: *Conophis vittatus* (Fig. 41), *Pseudoboa coronata* (Fig. 72), *Siphlophis pulcher* (Fig. 77), and *Xenopholis undulatus* (Fig. 95). All other figured hemipenes are fully everted as confirmed by re-examination of the original material. The latter species do have a slightly bilobed hemipenis whereas *X. scalaris* shows a clearly unilobed organ.

The differential length of the lobes seen in *Phalotris nasutus* (Zaher 1999: Fig. 63) and several species of *Philodryas* is a natural condition, not the result of partial eversion. The hemipenes of *Helicops leopardinus* (Fig. 47), *H. modestus* (Fig. 48), and *Philodryas aestiva* (Fig. 65), that might be interpreted as partially everted organs, are actually fully everted and expanded. Similarly, and contrary to Dowling's belief, the hemipenis of *Hydrops martii* (Fig. 52) is fully everted and expanded. Unlike the hemipenis of *H. martii* figured by Dowling (2002: Fig. 4B), which shows lobes with distally flattened surfaces, the hemipenis figured by Zaher (1999: Fig. 52) has rounded and expanded lobes. The flounces seen on the asulcate surface also represent a natural condition of the organ (Zaher 1999: 62).

Acknowledgments—We thank Charles Myers, John Cadle, and Roy McDiarmid for comments and criticisms on the manuscript, and Francisco Franco who made available specimens from the Instituto Butantan for hemipenial preparation. This research is supported by grants no. 01/00162-3 from FAPESP (Fundação de Amparo à Pesquisa do Estado de São Paulo) and no. 301298/1994-7 from CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnológico) to the senior author.

Whereas bites by viperid and elapid snakes have long been recognized as an important public health problem in Brazil (Ministério da Saúde. Fundação Nacional da Saúde 1998), bites by other snakes have received much less attention. Nonetheless, reports of symptomatic bites by supposedly non-venomous snakes in Brazil have appeared throughout this century (Martins 1916; Penteado 1918; Vital Brazil and Vellard 1926). Interest in colubrid bites increased after the herpetologists Karl Patterson Schmidt and Robert Mertens were killed by African snakes in the genera *Dispholidus* and *Thelotornis*, respectively (Nahas et al. 1976).

Symptomatic bites by colubrid snakes were reviewed by Minton (1990). Since then, additional species of colubrid snakes have been reported to cause symptomatic bites. These include several life-threatening bites to infants by *Boiga irregularis* (Fritts et al. 1990, 1994), and two serious bites by *Hydrodynastes gigas*, resulting in repeated episodes of collapse and paralysis in one case (Manning et al. 1999) and a "permanently disfigured" arm in another (Stevens 2000).

Apart from *Dispholidus* and *Thelotornis*, *Rhabdophis tigrinus* (Mittleman and Goris 1974; Zotz et al. 1991) has also caused fatal bites, and more recently, a fatal bite by *Philodryas olfersii* was reported (Fowler and Salomão 1994; Salomão and Di-Bernardo 1995). Controversies about the capacity of some colubrids, such as the South American *Tachymenis peruviana*, to kill humans remain. Lema (1978a) reported a case of fatal bite by *T. peruviana*, citing Vellard (1955). However, Vellard (1955) did not mention symptoms in humans, but only discussed the potent effects of *T. peruviana* venom in animal experiments. Serious bite symptoms by this species have been described by Schenone and Reyes (1965). Finally, *Boiga forsteni* is also suspected to have caused fatal bites in Sri Lanka (Fritts and McCoid 1999).

During the 1980s and 1990s certain colubrids thought to possess toxic saliva or venom (see Kochva 1987 for considerations on this matter) were identified (Hill and Mackessy 2000; McKinstry 1978, 1983; Minton 1990; Spawls and Branch 1995), based on the histological observation of their Duvernoy's glands, carried out by Taub (1967), Kochva and Gans (1970), Gabe and Saint-Girons (1971), and the descriptions of clinical manifestations in patients bitten by these snakes. Minton (1990) listed, summarized, and divided these symptoms into two basic categories: systemic poisoning associated with coagulopathy and those that presented local effects.

In Brazil, the number of reports on bites from "non-venomous" snakes has increased considerably and snakebites by "harmless" snakes are now considered a problem of public health. Among all the snakebites registered in the State of São Paulo (Fan and Cardoso 1995) and those caused by crotaline snakes in the city of Uberlândia, State of Minas Gerais (Silveira and Nishioka 1995), approximately 40% did not develop symptoms of envenomation, possibly because the snake was nonvenomous or, if it was venomous, the skin was not deeply punctured or no venom was injected (so called "dry bite") (Albolea 1999; Albolea and Salomão 1998; Ministério da Saúde. Fundação Nacional da Saúde 1998; Santos-Costa et al. 2000).

Examples of snakes which have caused human envenomations with serious clinical manifestations are the opisthoglyphous species *Phalotris lemniscatus* (= *Elapomorphus bilineatus* according to Ferrarezzi [1993]) (Lema 1978b); *Philodryas olfersii* and *P. patagoniensis* (Araújo and Santos 1997; Brito and Carvalho 2000; Campbell and Lamar 1989; Fowler and Salomão 1994; Nickerson and Henderson 1976; Nishioka and Silveira 1994; Salomão and Di-Bernardo 1995; Silva and Buononato 1983/84), *Clelia clelia plumbea* (Pinto et al. 1991) and the aglyphous *Liophis miliaris* (Santos-Costa and Di-Bernardo 1997) and *Helicops modestus* (Albolea and Salomão 1998; Albolea et al. 2000).

This paper is a report on bites caused by snakes other than pitvipers and coral snakes. It includes the frequency of snakebite per year, the identification of the snake species implicated, the profile of victims (age and sex) and clinical manifestations, as an aid in evaluation and prevention of this problem in Brazil.

The Hospital Vital Brazil (HVB), Instituto Butantan, São Paulo, provides free treatment for patients bitten by snakes. Some patients still possessed the snake (live or dead) which caused the snakebite, therefore an immediate identification could be done,

helping doctors make decisions about the use of antivenom. Snakes would then be deposited in the museum collection of the Laboratório de Herpetologia, Instituto Butantan, which contains only snakes responsible for biting humans and subsequent hospitalization of these patients. Data concerning information about the snake, the patient, and the snakebite itself are recorded by the museum and in HVB reports for each patient. A survey of the specimens, museum data, and medical reports allowed us to collect detailed information on the most common snakes involved, patient profiles, and most frequent symptoms. We emphasize that most snakebite victims at HVB come from the state of São Paulo and our conclusions may not apply to other states in Brazil. However, registers from the state of São Paulo are the most complete data sets in Brazil, being used by health authorities as a national reference because a lack of information on this subject from other states.

Hospital Vital Brazil started its activities in 1946. However, routine registration of snake species began only in 1959. Since then, HVB admitted a total of 6048 snakebite victims in which the offending snake accompanied the patient and was available for identification (Table 1). Of these, 4083 were inflicted by elapid and viperid snakes, 42 were inflicted by snakes of the families Anomalepididae, Boidae, and Leptotyphlopidae, and 1923 were caused by snakes in the family Colubridae (Table 2). Among the colubrids, the largest number of snakebites was caused by the genera *Helicops*, *Philodryas*, and *Liophis* (Table 3).

We found that male patients predominated in 11 of the 16 genera investigated. Snakes belonging to five genera—*Tomodon*, *Tropidodryas* ($\chi^2 = 4000$, $P = 0.045$, d.f. = 1), *Liotyphlops*, *Erythrolamprus* ($\chi^2 = 11560$, $P < 0.001$, d.f. = 1), and *Apostolepis* ($\chi^2 = 36000$, $P < 0.001$, d.f. = 1)—bit significantly more female patients.

TABLE 1. Frequency of snakebites registered at Hospital Vital Brazil, Instituto Butantan.

Year	Viperids and Elapids		Others		Total	
	N	%	N	%	N	%
1959	52	64.2	29	35.8	81	1.34
1960	64	68.1	30	31.9	94	1.55

Total	**4083**		**1965**		**6048**	**100.0**

Patients between 0 and 40 years of age were the main victims of colubrid bites, particularly of *Helicops* ($\chi^2 = 23.604$, $P < 0.0001$, d.f. = 1) and *Philodryas* ($\chi^2 = 10.071$, $P < 0.0015$, d.f. = 1). Snakes belonging to the genera *Xenodon*, *Liophis*, *Philodryas*, *Atractus*, *Chironius*, *Waglerophis*, *Helicops*, and *Thamnodynastes* bit more patients between 15 and 40 years old. Children under 14 years old were the main victims of *Liotyphlops*, *Mastigodryas*, *Tropidodryas*, *Oxyrhopus*, *Waglerophis*, and *Helicops* (Table 4). Hands, arms, feet, and legs were the most frequently bitten parts of the body. Snakes of the genera *Atractus*, *Mastigodryas*, *Philodryas*, *Thamnodynastes*, and *Xenodon* bit hands and arms 60.0% of the time, whereas species of the genera *Helicops* ($\chi^2 = 5.22$, $P = 0.0223$, d.f. = 1), *Liotyphlops*, *Tropidodryas*, *Apostolepis*, and *Waglerophis* bit feet and legs more often. The high frequency of *Helicops* bites on feet and legs must be a consequence of the aquatic habits of these snakes, associated with the fact that people do not use protection to walk in the water, especially when fishing. Bites to the trunk were reported for *Erythrolamprus*, *Tomodon*, *Apostolepis*,

and *Tropidodryas*. Most of these bites to the middle of the body occurred when the victim was either in bed or having a bath (Table 5).

The main clinical manifestations exhibited by patients (Table 6) were abrasions (sometimes with bruising) and local pain, followed by local hemorrhage from teeth punctures, swelling, and erythema. Other less significant symptoms included: stinging sensation, local numbness, general discomfort, hyperemia, local paleness, local itching, and sweating. Ecchymoses and gum hemorrhage occurred only in patients bitten by *Philodryas* (Table 7).

Recently (September 2000) a herpetologist from Instituto Butantan was bitten by *Liophis poecilogyrus* on his left fourth digit and thereafter exhibited local effects such as intense pain (particularly throbbing), swelling, local hemorrhage, lack of sensitivity, and local decrease of temperature. These symptoms lasted for three hours (C. A. Falcetti, pers. comm.).

Some of these manifestations are very similar to those exhibited by patients bitten by pitvipers, and this may confuse inexperienced doctors. An example of this is the case of a man, 53 years

TABLE 2. Percentage of snakebites among different families of snakes at Hospital Vital Brazil from 1959 to 1999.

Family	Number of snakebites	(%)
Viperidae	4050	66.96
Colubridae	1923	31.80
Elapidae	33	0.55

Tropidodryas	16.7	0	83.3
Erythrolamprus	33.3	33.3	33.4

TABLE 6. Percentage of pathologies presented by patients bitten by mildly venomous snakes admitted to Hospital Vital Brazil from 1959 to 1999.

Pathology	%
Abrasions	30.67
Local pain	28.09
Local hemorrhage	13.40
Swelling	10.05
Erythema	8.25
Discomfort	4.90
Stinging sensation	1.28
Ecchymosis	0.77
Numbness	0.77
Gum hemorrhage	0.52
Hyperemia	0.52
Local paleness	0.26
Local itching	0.26
Sweating	0.26

old (HVB number 73386) bitten by *Helicops*, who was admitted to the hospital and received four vials of bothropic antivenom, because of coagulopathy. Bothropic antivenom was also given to a patient (HVB number 48575), bitten by *Liophis miliaris*, who presented serious symptoms of hemorrhage. On another occasion a 17-year-old boy was admitted with all the symptoms of *Bothrops* envenomation. However, he claimed he had been bitten by a green snake with brown head, which unfortunately he had not managed to catch. When a *Philodryas olfersii* was shown to him, he identified it immediately, which avoided the administration of bothropic antivenom (G. Puorto, pers. comm.).

Colubrids produce the greatest number of bites in relation to their abundance in neotropical regions, compared to other families (Cadle and Greene 1993; Ferrarezzi 1994; McDowell 1987; Vanzolini 1986). In India 80% of reported snake bite cases are caused by "mildly venomous" snakes, particularly a common water snake (*Cerberus rhynchops*) (Saha and Hati 1998). Aquatic snakes of the genus *Helicops* caused most snakebites registered in the state of Rio Grande do Sul, in southern Brazil (Costa 1997). A possible explanation for this is the defensive behavior exhibited by species of *Helicops* (Cei 1993) when compared to species of other genera. Bites to the feet and legs are more frequent because farm workers often do not wear shoes. A similar situation has been found regarding colubrid bites reported by Minton (1996), Costa (1997), and Saha and Hati (1998). Snakebites involving *Helicops* and *Liophis* occurred predominantly near or in the water, where snakes are difficult to see because of cryptic coloration. Snakes of other genera such as *Waglerophis*, *Chironius*, *Apostolepis*, *Tropidodryas*, and *Tomodon* can also have a cryptic color pattern, thus increasing the probability of bites. This is because people typically touch or step on them without realizing their presence. Alternately, brightly patterned species might inflict more bites because of their attractiveness and increased liklihood of being handled. This seems to be the case with species of *Philodryas*, *Apostolepis*, and *Erythrolamprus*, as many patients admitted they were bitten when attempting to capture snakes.

Blind snakes (*Liotyphlops*) have not been reported to bite humans. Data presented here show that children were most frequently involved in these encounters (66.7%), probably because they play on the ground, digging up soil and often have bare feet (part of the body most affected—85.7%). Many parents indicated that the child was playing with the snake. This shows a close correlation between the fossorial habits of this snake, and the situation in which the encounter occurred. However, despite the number of cases (N = 28), the medical reports of these patients described only abrasions and local pain.

Local hemorrhage is one of the most common pathologies produced by snake venom. Proteolytic activity at various levels, high phospholipase A (2) activity, phosphodiesterase and acetylcho-

TABLE 7. Distribution of main clinical manifestations (%), shown by patients admitted to Hospital Vital Brazil, Instituto Butantan, among the different genera of mildly venomous snakes. (SS – stinging sensation; LP – local pain; N – numbness; SL – swelling; EC – ecchymosis; ER – erythema; A - abrasions; GD – general discomfort; GH – gum hemorrhage; HY – hyperemia; HE – local hemorrhage; PL – local paleness; LI – local itching; SW – sweating).

linesterase activities, have been found in the "venom" (Duvernoy's secretion) of twelve species of colubrid snakes (Hill and Mackessy 2000). Bioassays using mice (18–22 g) have shown that the species *Apostolepis dimidiata*, *Phalotris lemniscatus*, *Elapomorphus quinquilineatus*, *Erythrolamprus aesculapii*, *Thamnodynastes strigilis*, and *Liophis miliaris* have highly hemorrhagic "venoms" (M. G. Salomão, pers. obs.). Such reactions in mice were similar or more intense than those resulting from *Philodryas olfersii*, whose Duvernoy's secretion causes quantitatively more hemorrhaging than the venom of many species of *Bothrops* (Assakura et al. 1992; Salomão 1991). Local hemorrhage is normally a consequence of skin perforation combined with venom effects. *Philodryas* is an exception because bites cause significant systemic coagulopathy such as gum hemorrhage.

Experiments using the saliva of *Helicops* (0.0725 mg dried venom/g mice) killed mice in 10 minutes, with the mice exhibiting spasms and distension of posterior legs. When tested on fish (4–6 g), their usual prey, it caused a decrease of opercular beatings and general immobilization for about 30 minutes, followed by death (Albolea 1999; Albolea et al. 2000). Paralysis was also observed when extract of the Duvernoy's glands of *Sibynomorphus neuwiedi* (Laporta-Ferreira 1985) and of *S. mikani* (Salomão and Laporta-Ferreira 1994) were used on snails and slugs, respectively.

Other symptoms, such as general discomfort (e.g., headache, nausea, dizziness) and sweating may be a consequence of psychological effects of encountering a snake. These results show a relationship between the effects of venom on prey and certain symptoms present in victims of bites from "mildly venomous" species. Moreover, additional laboratory studies should be undertaken to determine if other snake species, presently considered nonvenomous, might have "venoms" of medical significance to humans (Nishioka and Silveira 1994).

Our results have documented the potential danger of certain Brazilian colubrid snakes to humans. Several taxa, in particular *Philodryas olfersii* and at least some species of *Phalotris* and *Apostolepis*, and possibly *Hydrodynastes gigas*, can cause potentially life-threatening illness. The adjective "harmless" should be abandoned when referring to colubrids. We suggest the designation of "mildly venomous" (Minton 1990) to refer to those snakes which are known to produce toxic symptoms and recommend the use of "non-venomous" exclusively for those species which lack Duvernoy's glands. Moreover, we feel people should be advised not to handle snakes unnecessarily, mainly because the effects of the "venom" of many species are completely unknown and even those species, such as boids, which do not inject toxic saliva may cause serious injuries (see Duarte et al. 2000 for details on attacks by boids). Campaigns such as those carried out in Instituto Butantan to teach people about the importance of snakes in the environment, despite their potential danger to humans, should be encouraged and implemented in other states. Training for doctors and nurses for immediate snake identification should be reinstituted; such training would minimize unnecessary administration of antivenom, and consequently, antivenom side effects (see Nishioka and Silveira 1994 for more examples). Studies on natural history should focus on epidemiological aspects of colubrid species to better understand their behavior, consequences of interaction with people, and thereby reducing risks of snakebite to the public. Finally, the idea of preparing a specific antivenom for some colubrid snakes, as suggested by Lema (1978a, b) and Salomão (1991) should be considered on the basis of its cost/benefit ratio, despite the logistic difficulties of venom extraction from colubrid snakes (Salomão et al. 1990).

Acknowledgments.—We thank Wolfgang Wüster for discussions and revision of the manuscript, and donation of reprints on this subject. We also thank David Hardy, Sr. and Emmett Blankenship for reviewing several drafts of the ms. Finally, we thank Francisco do Carmo Costa for help with final revision of the ms.

The Mexican lance-headed rattlesnake (*Crotalus polystictus*) is distributed across the Mexican Plateau and has been documented from the states of Veracruz, Puebla, México, Distrito Federal, Michoacán, Querétaro, Guanajuato, Jalisco, and Zacatecas (Campell and Lamar 1989). Few data exist on the natural history of this species. Armstrong and Murphy (1979) provided habitat descriptions, behavioral observations, and morphometric data on several gravid females and their offspring. Other records of reproduction in *C. polystictus* were reported in Klauber (1972) and Hubbard (1980). Klauber (1972) stated that one specimen of *C. polystictus* contained mammal hair, and in another a small passerine bird and a small mammal. Specimens have been found in mesquite-grassland (Duellman 1965), plains-grassland, on plateaus in breaks in pine-oak forest (Armstrong and Murphy 1979), and in pine-oak forests (Campbell and Lamar 1989). McCranie and Wilson (2001) reported finding a female and six young near a stream in a cornfield in Aguascalientes. The historical range of *C. polystictus* may be declining because of the conversion of this species' native habitat to farmland and habitat destruction (Armstrong and Murphy 1979; Greene and Campbell 1992). The draining of Lago de Chapala also might have caused a decline in the number of *C. polystictus* (Duellman 1961). Greene and Campbell (1992) listed this species as "vulnerable to extinction" because of habitat conversion and its restricted distribution.

The region of central México situated on the Mexican Plateau west of the Sierra Ajusco between Toluca and Atlacomulco is characterized by vast monocultures of corn fields. In mid-August 2001 we spent four days in the environs several kilometers north of Ixtlahuacán, México. This area lies at an average elevation of 2500 m and is relatively flat. Approximately 25 individuals of *C. polystictus* were observed. Most were found along a small stretch of earthen canal (ca. 50 m long) bordering a dirt road between two fallow corn fields. The canal averaged 1.5 m deep and 2 m wide, and was covered by thick vegetation. There was no running water in the bottom of the canal, though standing pools of water up to ca. 30 cm deep in places were present. Rodent burrows were found on the steep canal sides. Several other specimens of *C. polystictus* (including a female with neonates) were found ca. 1 km from the canal on top of a grassy earthen berm next to a cornfield.

All specimens were observed from 1115 h to 1815 h CST. On 10 August 2001 we were in the field from 9000 h until 1500 h. After 10 August all our search times were limited to the late afternoon and early evening (1500–1900 h). Cooler temperatures (< 15°C), cloudiness, and rain in the early evening limited *C. polystictus* activities. An adult male was found active at 1815 h before it started raining, and nocturnal activity, such as that found by Armstrong and Murphy (1979), is probable when environmental conditions are favorable. Specimens were located in a coiled position basking in direct sun in the morning and early afternoon. Often these basking individuals were found coiled on top of bunchgrass (zacatón). Most specimens observed in the late afternoon and early evening were found actively crawling or in a semi-coiled position out of the direct sunlight, when it was present. Upon collection, specimens were restrained in clear plastic tubes for ease of handling and to verify sex and reproductive condition.

Adult *C. polystictus* were alert and difficult to approach. Specimens observed from a distance often laid motionless before being approached to within a few meters, at which time they would rapidly retreat into burrows. Several specimens that were first observed perched on zacatón retreated into the water of the canal and could be heard or were seen swimming away. Klauber (1972) reported that Paul D. R. Ruthling found *C. polystictus* in the tules of Lake Chapala that sought refuge in the water. These behaviors contrast with those found in *C. polystictus* by Armstrong and Murphy (1979), who found these rattlesnakes to "generally not retreat when approached" during the summer.

Reproduction and mating behaviors in *C. polystictus* were observed. A female was found basking with six neonates on top of her at 1115 h on 10 August 2001. The air temperature was 17.4°C. Upon discovery the neonates and female took refuge under a nearby concrete fence post. Though no length measurements were taken, the female weighed 122 g and the combined weight of the neonates was 52 g. The neonates shed a few days later. At 1232 h later that day an adult female (167 g) was found with four neonates coiled next to her, one of which was shedding, on the steep side of the earthen canal in thick vegetation in partial shade. However, gentle palpation of the female revealed she was gravid. She gave birth to two live and two stillborn neonates and four infertile ova on 21 August 2001. No data were recorded on the litter.

Reproductive associations were observed in *C. polystictus* on several occasions. On 10 August 2001 at 1245 h an adult male (306 g) was found stretched out on top of an adult female (108 g) on the side of the earthen canal underneath a small bush. The male was collected but the female escaped into a rodent burrow. She was observed again at 1406 h below the rodent burrow coiled on top of another adult male. She was collected but the male escaped into the burrow. This female had shed after the first observation of her prior to being collected. The fresh shed skin was found near the entrance to the burrow and a small piece was stuck to her. The second male (identified by his unique dark coloration and large size) remained outside the entrance to the rodent burrow and was observed here for several days. On 14 August 2001 at 1750 h this male was found outside the entrance to the burrow alongside another adult male. The shedding of the female and release of pheromones may have stimulated the male courtship behavior, as dis-

cussed in Schuett (1992) and Aldridge and Duvall (2002).

This population of *C. polystictus* lies within an artificial, highly-modified habitat. Such an area may provide an increase in prey availability because of high rodent densities typically associated with agricultural areas. Several of the scats from wild collected individuals examined in the lab contained rodent hair (species not identified). Specimens were most commonly encountered near heavily vegetated earthen canals and berms. The monoculture created by hectares of uninterrupted cornfields contain unsuitable habitat, and thus concentrate populations of *C. polystictus* along breaks in their periphery. The use of agricultural chemicals and pesticides and conversion of earthen canals to concrete canals may negatively affect this population. Searches near concrete canals failed to produce any specimens of *C. polystictus*, presumably because of their lack of rodent burrows and vegetated sides. Although this population of *C. polystictus* appears to be healthy, it should be considered fragile because of its location in an area subject to further modification for agriculture.

Acknowledgments.—We thank A. Kardon, K. Peterson, and J. Galvan for their assistance. J. Mueller, J. Dixon, M. Dorcas, and an anonymous reviewer reviewed the manuscript and provided additional comments. Research and collecting were conducted under the authority of SEMARNAT scientific research permit OFICIO NÚM/SGPA/DGVS/ 3394 issued to RWB.

The need for conservation and management of rare species is becoming increasingly important as wildlife species and their habitat continue to decline. Translocation of wild captured adults to augment and reintroduce populations has been successfully used for some endangered avian species (see Carrie et al. 1999; Rudolph et al. 1992). In general, success rates for mammals and birds are higher than those for amphibians and reptiles (Dodd and Seigel 1991; Griffith et al. 1989).

The Timber Rattlesnake (*Crotalus horridus*) is listed as a State of Texas threatened species and translocation of captive raised snakes might benefit small populations. Controversy exists on the benefits versus problems associated with translocation of amphibians and reptiles (Burke 1991; Dodd and Seigel 1991; Reinert 1991). A recent evaluation of the impacts of translocation on behavior and survival of mature *C. horridus* suggests that translocation of adult snakes not be recommended as a standard management technique because of immediate aberrant movement behavior patterns and long-term elevated rates of overwinter mortality, predation, and disease (Reinert and Rupert 1999).

Because of the problems associated with translocation of adult *C. horridus*, the ability to successfully raise neonate rattlesnakes and successfully introduce them into forest habitat may be an essential conservation technique if viable populations of this rare species are to be maintained in the wild. If captive-raised neonates can be grown to sufficient size, predation-related and overwinter mortality events suffered by neonates and first-year juveniles might be minimized, increasing the net survival rates of cohorts released to the wild.

We captive raised one neonate *C. horridus* in 1993–1994 and eight in 1994–1995, recording detailed growth data on the eight snakes over an 11-month period. The nine snakes were released with surgically implanted transmitters in eastern Texas and we monitored their movements for six years. We determined their survival rates in the wild to evaluate the possible merit of using captive-raised neonates to augment small, isolated populations.

Materials and Methods.—Locations of released *Crotalus horridus* with transmitters were monitored in the Stephen F. Austin Experimental Forest, southern Nacogdoches County (31°29'N,

THAMNOPHIS MARCIANUS (Checkered Garter Snake). **SALVAGING PRENEONATES FROM A ROAD-KILL.** The results of salvaging unborn or preneonate young of natricine snakes from road-killed gravid females does not seem to be recorded in the literature. Pope (1952. Snakes Alive and How They Live. The Viking Press, New York. 238 pp.) suggested that the young of a gravid female live-bearing snake, cut open a few days before normal birth, would survive, and that snakes are often killed with enough force to set any well developed young free. Oliver (1955. The Natural History of North American Amphibians and Reptiles. V. Van Nostrand Co., Princeton, New Jersey. 359 pp.) agreed, commenting that if a female carrying young about to hatch, was vigorously clubbed, her swollen body might burst, releasing the young. Accounts of unborn young surviving their mother's death are exemplified by J. T. Burkhart (pers. comm.) who related an account of a *Thamnophis* sp. being run over by a vehicle, expelling numerous young that subsequently crawled away.

This is a report on salvaging preneonate young from a road-killed checkered garter snake, *Thamnophis marcianus*. The specimen was collected from Willow Road in extreme northwestern Enid, Garfield County, Oklahoma, USA at 2059 h (after dark) on 29 September 1995. Abdominal movement was observed in the snake that did not seem to be characteristic reflex action. The snake was hurriedly opened surgically at 2110 h, and 25 preneonate young were removed by 2233 h. Seven young exhibited life signs such as mouth gaping, tongue flickering, and body movements.

The total length of the parent female was 65.5 cm. (SVL 51.2 cm, tail 14.3 cm). Three of the 25 young were accidentally mutilated during hasty surgery, and were not measurable, another remained in its embryonic sac and was not measured. Total lengths of 21 remaining young varied from 15.1 to 20.4 cm, averaging 17.9 cm. Total lengths of the five surviving live young was 17.0 to 20.4 cm, averaging 10.04 cm. Three of these died by 23 December 1995. Two remaining juveniles have survived.

Specimens were deposited in the museum collections of St. Gregory's University, Shawnee, Oklahoma, SGU numbers 510 (adult female), and young 511–528, 534, 560 and 2038.

Submitted by **RICHARD L. LARDIE**, P.O. Box 9002, Vance AFB, Enid, Oklahoma 73705, USA.

GEOGRAPHIC DISTRIBUTION

Instructions for contributors to Geographic Distribution appear in Volume 34, Number 2 (June 2003). Additional note: The responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extensions unless a thorough literature review has been completed.

CAUDATA

AMBYSTOMA OPACUM (Marbled Salamander). USA: VIRGINIA: Scott Co: Rikemo Lodge, ca. 1 km SW of Dungannon. 8 May 1999. Christopher S. Hobson, Steven M. Roble, Anne C. Chazal. Verified by Richard Hoffmann. Virginia Museum of Natural History (VMNH) 10337. One sub-adult was found in a small pit (ca. 0.25 m deep) covered by a piece of plywood at Rikemo Lodge, situated on a slope just above the floodplain of the Clinch River. First record for Scott Co., and first published record for southwestern Virginia (Mitchell and Reay 1999. Atlas of Amphibians and Reptiles in Virginia. Spec. Publ. No. 1, Virginia Department of Game and Inland Fisheries, Richmond, Virginia. 122 pp.; Tobey 1985. Virginia's Amphibians and Reptiles: A Distributional Survey, Virginia Herpetological Survey, Purcellville, Virginia, 113 pp.). The nearest published records within the Ridge and Valley physiographic province are from Knox Co., Tennessee (ca. 160 km SW), and Montgomery Co., Virginia (ca. 180 km NE) (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, Center for Field Biology, Austin Peay State University, Clarksville, Tennessee, 94 pp.; Tobey 1985, *op. cit.*). This record partially fills a hiatus in the known range for this species that includes much of the southern Appalachians.

Submitted by **CHRISTOPHER S. HOBSON** (e-mail: cshobson@dcr.state.va.us) and **STEVEN M. ROBLE** (e-mail: sroble@dcr.state.va.us), Virginia Department of Conservation and Recreation, Division of Natural Heritage, 217 Governor Street, Richmond, Virginia 23219, USA.

AMBYSTOMA TIGRINUM TIGRINUM (Eastern Tiger Salamander). USA: ILLINOIS: Gallatin Co: pond NW side York Lane and 1.3 km E Pounds Hollow Road (37°36'20"N, 88°15'34"W). 7 June 2002. Kurt J. Regester and David W. Butler. Verified by Ronald A. Brandon. SIUC H–07089. Larval specimens collected in Shawnee National Forest wildlife pond. New county record (Philips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, Champaign, Illinois. xii + 282 pp.).

Submitted by **KURT J. REGESTER** and **DAVID W. BUTLER**, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA.

CRYPTOBRANCHUS ALLEGANIENSIS ALLEGANIENSIS (Eastern Hellbender). USA: TENNESSEE: Cheatham Co.: Sycamore Creek adjacent to Harris Town Road, ca. 4.0 air miles NW of Ashland City (36°19'39"N, 87°05'40"W). 10 July 1996. Brian Canada. Austin Peay State University Museum of Zoology (APSU 5455 B series of 10 color photos). Verified by David H. Snyder. One adult (total length 727 mm) in shallow water (< 10

cm) where small spring-fed waterfall trickles over limestone ledges and enters stream. New county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, Center for Field Biology, Austin Peay State University, Clarksville, Tennessee) that fills gap between records from Montgomery and Davidson counties.

Submitted by **BRIAN CANADA**, 431 Van Hook Drive, Ashland City, Tennessee 37015, USA (e-mail: Brian.Canada@state.tn.us), and **A. FLOYD SCOTT**, Department of Biology and Center for Field Biology, Austin Peay State University, Clarksville, Tennessee 37044, USA.

EURYCEA LONGICAUDA (Long-tailed Salamander). USA: MISSOURI: Maries Co: 0.7 km N–3.4 km E jct of US 63 and MO 42 in Vienna (38°11'32"N, 91°54'35"W). 25 April 1971. J. Puricelli. Verified by R. W. Axtell. SIUE 752. New county record.

Submitted by **CAROL A. BRYANT**, 7841 South Panther Creek Road, Mount Olive, Illinois 62069, USA; e-mail: cabryant@ctnet.net.

EURYCEA LUCIFUGA (Cave Salamander). USA: MISSOURI: Reynolds Co: Johnson Shut-Ins State Park campgrounds (37°32'20"N, 90°50'30"W). 4 May 1963. C. Glaeser. Verified by R. W. Axtell. SIUE 969. New county record.

Submitted by **CAROL A. BRYANT**, 7841 South Panther Creek Road, Mount Olive, Illinois 62069, USA; e-mail: cabryant@ctnet.net.

EURYCEA LUCIFUGA (Cave Salamander). USA: INDIANA: Franklin Co: Mounds State Recreation Area, rocky seep, 1.4 km NE of top of "The Mounds." 24 April 2001. Rhys Dale, under permit to John Iverson. Verified by John Iverson. Florida Museum of Natural History, University of Florida (UF 134743). Extends range 9.0 km NNE of previous record (Brookville; Minton 2001. Amphibians and Reptiles of Indiana. Indiana Acad. Sci., Indianapolis, 404 pp.).

Submitted by **STESHA A. PASACHNIK**, Earlham College, Richmond, Indiana, 47374, USA; e-mail: pasacst@earlham.edu.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander). USA: MICHIGAN: St. Clair Co: Pond in woodlot south of Marysville along Highway 29, 1 km NW of jct with Davis Road (42°53.3'N, 82°29.3'W). 24 April 2002. Richard Lehtinen, Glenn Fox, Keith Pecor, and Greg Schneider. Verified by Ronald A. Nussbaum, University of Michigan Museum of Zoology (UMMZ 229576). Extends range northwards into the "thumb" of Michigan.

Submitted by **RICHARD LEHTINEN**, **GLENN FOX**, **KEITH PECOR**, and **GREG SCHNEIDER**, University of Michigan Museum of Zoology, Ann Arbor, Michigan 48109–1079, USA.

ANURA

BATRACHYLA NIBALDOI (Nibaldo's Wood Frog). CHILE: X REGION DE LOS LAGOS: Quinchao, Isla Alao (42°35'S, 73°16'W, 114 m elev.), ca. 6 km N of Isla Chaulinec. 13 and 18 February 2001. L. Iriarte. Museo Nacional de Historia Natural, Santiago, Chile (MNHN 3422 and 3421). Verified by H. Núñez. Collected on mosses in a Chilean Valdivian rain forest. Species previously known in Chile from Puente Traihuanca (Formas 1997. Herpetologica 53:6–13). Subsequent records extended the range to Laguna San Rafael National Park (Díaz-Páez and Williams 2001. Herpetol. Rev. 32:189) and Las Guaitecas National Reserve (Díaz-Páez and Carreño 2002. Herpetol. Rev. 33:218). This specimen represents the first record from X Administrative Region of Chile; and extends the northern range of the species ca. 360 km NW from Puente Traihuanca.

Submitted by **DANIEL PINCHEIRA-DONOSO**, Sección Zoología, Museo Nacional de Historia Natural, Casilla 787, Santiago, Chile and **HELEN DÍAZ-PÁEZ**, Departamento de Zoología, Facultad de Ciencias Naturales y Oceanográficas, Universidad de Concepción, Casilla 160-C, Concepción, Chile.

BUFO CALIFORNICUS (California Arroyo Toad). MÉXICO: BAJA CALIFORNIA NORTE: Río San Rafael, Cañon San Rafael, 18 air km E Punta Colonet (31.09876°N, 116.2539°W), 200 m elev. 25 May 2002. Los Angeles County Museum of Natural History voucher photographs (LACM–PC 1390). Río de Las Palmas, Cañon el Alamo, 6.5 air km NE El Testerazo (32.33030°N, 116.51396°W), 450 m elev. 23 March 2002. (LACM–PC 1391); and Río los Encinitos, Cañon la Grulla, 1 air km NW Uruapan (31.63665°N, 116.46570°W), 175 m elev. 5 April 2002. (LACM-PC 1392). Observed by Diego Casas, Hector Cevallos, Gustavo Danneman, Brian Freiermuth, Robert Lovich, Clark Mahrdt, Mark Mendelsohn, Jeff Saurwein. All photos verified by Edward L. Ervin. This species ranges west from the Sierra Juárez and Sierra San Pedro Mártir peninsular range to the foothills and coastal plains of northwestern Baja California, and south to San Quintín (Grismer 2002. Amphibians and Reptiles of Baja California including its Pacific Islands and the Islands in the Sea of Cortés. University of California Press, Berkeley and Los Angeles, California). Both adults and larvae of *Bufo californicus* were previously reported by Welsh (1988. Proc. California Acad. Sci. 46:1–72) from the upper Río San Rafael drainage in the western foothills (1330 m elev.) and conifer forest (2210 m elev.) of the Sierra San Pedro Mártir. The Río San Rafael population reported here represents a new coastal record for this drainage, located ca. 65 km downstream from the foothill locality reported by Welsh (1988, *op. cit.*). Several paedomorphs in addition to *Hyla regilla* and *H. cadaverina* tadpoles were observed at the site along a 200 m portion of stream. An adult male (SVL 55 mm; 27g) was observed in the Río de las Palmas in association with introduced adult *Xenopus laevis* and adult *H. regilla*, and *H. cadaverina*. Although Grismer (2002, *op. cit.*) does not include *X. laevis* as occurring in Baja California, Tinsley and McCoid (1996. *In* R.C. Tinsley and H. R. Kobel [eds.], The Biology of *Xenopus*. Symposia of the Zoological Society of London, No. 68, pp. 81–94, Clarendon Press, Oxford) indicate that this species may occur in large populations in the Municipality of Tijuana, Baja California, Mexico. This record of *X. laevis* confirms the species presence in the Rio las Palmas watershed and represents the southernmost record in Baja California. In the Río los Encinitos drainage, an adult male arroyo toad (SVL 54 mm; wt.17 g) was observed with several adult H. regilla. The Río de las Palmas and Río los Encinitos records represent new river drainages for the arroyo toad (see Mahrdt et al. 2002. Herpetol. Rev. 33:123–125) and potential breeding sites of *Bufo californicus*

in Baja California.

Submitted by **CLARK R. MAHRDT**, Herpetology Department, San Diego Natural History Museum, P.O. Box 1390, San Diego, California 92112, USA, **ROBERT E. ZIMMITTI**, P&D Environmental, 401 West "A" Street, San Diego, California 92101, USA, and **GUSTAVO D. DANEMANN**, Pronatura Noroeste, Riveroll No. 724, Ensenada, Baja California, CP 22800 México.

BUFO MARINUS (Cane Toad): BRITISH WEST INDIES: Cayman Islands: Grand Cayman: Georgetown; Melody Lane off Crewe Road (under a pile of brush). 18 June 1999. David Arch, Jr. Verified by R. Powell. Photographic documentation (by the senior author): Milwaukee Public Museum (MPM) Herp Photo 710. First record of this genus from the Cayman Islands (Seidel and Franz 1994. *In* M. A. Brunt and J. E. Davies [eds.], The Cayman Islands: Natural History and Biogeography, pp. 407–433. Kluwer Academic Publ., Dordrecht, Netherlands). The previous summer, Mr. Geddes Hislop, a Trinidadian naturalist familiar with the species, had observed another individual on the grounds of the Catholic School on Walkers Road. The specimen reported here was the subject of an article and accompanying photograph in the *Caymanian Compass* newspaper on 23 June 1999. Subsequently, the National Trust for the Cayman Islands and the Cayman Department of Agriculture received many telephone calls from the public that suggest that the species is established from West Bay to Bodden Town. One respondent stated that he had first observed it five years earlier. These reports probably have merit because no other bufonid occurs in the Cayman Islands; the only other relatively large anuran resident in the islands is the distinctive *Osteopilus septentrionalis* (Cuban treefrog). No reports were received from East End or North Side on Grand Cayman. The source of the introduction is unknown. The species has not been reported from Cayman Brac or Little Cayman.

Submitted by **F. J. BURTON**, P.O. Box 10308 APO, Grand Cayman, Cayman Islands, British West Indies (e-mail: fjburton@candw.ky), and **A. C. ECHTERNACHT**, Department of Ecology & Evolutionary Biology, University of Tennessee, Knoxville, Tennessee 37996-1610, USA (e-mail: echterna@utk.edu).

BUFO NEBULIFER (Gulf Coast Toad). *Bufo nebulifer* was formerly part of *B. valliceps*, now restricted to Central and South America (Mulcahy and Mendelson 2000. Mol. Phylog. Evol. 17:173–189). USA: TEXAS: ANDERSON Co: In a small, semi-flooded pasture at the corner of Farm Road 321 and County Road 349 (31°52.205'N, 87°34.799'W). 29 May 2002. Matthew E. Gifford. This specimen will be deposited in the University of Texas at Arlington Collection of Vertebrates. (UTA A–55078) Verified by Ronald L. Gutberlet, Jr. *Bufo nebulifer* is widespread in eastern and central Texas. This species has never been recorded in Smith, Cherokee, Van Zandt, Rains, Upshur, and Rusk counties, however, it has been recorded from adjacent counties. Smith Co. has been extensively surveyed and has an extremely well documented herpetofauna with no evidence of the presence of *B. nebulifer*. The individual we collected in Anderson Co. represents a new county record (Dixon 2000. Amphibians and Reptiles of Texas,Texas A&M University Press, College Station Texas). No other *B. nebulifer* were located nearby, however, several large choruses of East Texas Toads, *B. woodhousii velatus*, were in proximity. *Bufo w. velatus* is relatively rare in the southern Texas counties where *B. nebulifer* is common, whereas dense populations of *B. w. velatus* occur in each of the counties where *B. nebulifer* has not been recorded. Further sampling is required to determine if the absence of *B. nebulifer* in these counties is a result of natural events or inadequate sampling.

LEPTODACTYLUS POECILOCHILUS (Turbo White-lipped Frog). COSTA RICA: HEREDIA: Cantón Sarapiquí: La Selva Biological Station (10°25.847'N, 84°00.201'W), 75 m elev. 26 April 2002. Andrew J. Crawford. Universidad de Costa Rica, Museo de

Zoología (UCR 16417). 20 June 2002. Eduardo Toral. La Guaria annex of La Selva reserve (UCR 16762). Both verified by Gerardo "Cachí" Chaves. First records (with vouchers) for Heredia and westernmost localities for the Atlantic versant of Costa Rica (Savage 2002. Amphibians and Reptiles of Costa Rica. Univ. of Chicago Press, Chicago. 934 pp.). Because La Selva is herpetologically the most thoroughly studied site in the country, we suspect that this species might be a recent arrival rather than a rare or overlooked species. *Leptodactylus poecilochilus* might be expanding its range because of local deforestation as the species is thought to prefer open and disturbed habitats (Savage, *op. cit.*).

Submitted by **ANDREW J. CRAWFORD**, Smithsonian Tropical Research Institute, Apto. 2072, Balboa, Ancón, Panama (e-mail: crawfordaj@naos.si.edu), **EDUARDO TORAL** (e-mail: guashote@yahoo.com), and **FEDERICO BOLANOS**, Escuela de Biología, Universidad de Costa Rica, San Pedro, Costa Rica.

MYERSIELLA MICROPS (NCN). BRAZIL: MINAS GERAIS: Municipality of Caratinga: Estação Biológica de Caratinga, (19°44'S, 41°49'W). November 2000. J. Cassimiro. Museu de Zoologia João Moojen de Oliveira, Universidade Federal de Viçosa, Viçosa, Minas Gerais, (MZUFV 4744–45). Verified by J. P. Pombal, Jr. Published distribution for the species is Atlantic forests in the states of Rio de Janeiro and São Paulo, in southeastern Brazil (Frost 2000. Amphibian Species of the World. An Online Reference. http://research.amnh.org/herpetology/amphibia/). First state record, also represents the most inland and northermost record for the species and extends known distribution ca. 350 km airline.

Submitted by **RENATO NEVES FEIO**, Museu de Zoologia João Moojen de Oliveira, Universidade Federal de Viçosa, 36571–000, Viçosa, MG, Brazil; **JOSE CASSIMIRO**, Departamento de Zoologia, Instituto de Ciencias Biológicas, Universidade Federal de Minas Gerais, 30123–970, Belo Horizonte, MG, Brazil and **CARLOS ALBERTO GONÇALVES DA CRUZ**, Departamento de Vertebrados, Museu Nacional, Quinta da Boa Vista, 20940-040, Rio de Janeiro, RJ, Brazil.

PLETHODONTOHYLA COUDREAUI (Coudreau's Frog). MADAGASCAR: Ambolokopatrika Forest, Campsite 3 (Antsinjorano), Andapa Fivondronana, Antsiranana Faritany (14°32.6'S, 49°25.8'E, ca. 950 m elev.), and Masoala Peninsula, Campsite 3 (Andasin'i Governera), Antalaha Fivondronana, Antsiranana Faritany (15°18'S, 50°01'E, ca. 650 m elev.). Collected 13 December 1997 by F. Andreone, G. Aprea, and J. E. Randrianirina (Museo Regionale di Scienze Naturali di Torino [MRSN] A2066: Fig. 1), and 2 December 1998 by F. Andreone and J. E. Randrianirina (MRSN A2115), respectively. Verified by M. Vences. *Plethodontohyla coudreaui* was described by Angel (1938. Bull. Mus. natn. Hist. nat. Sér. 2 10:260–261) from Betampona, eastern Madagascar (Toamasina Fivondronana, Toamasina Faritany: 17°52'–17°56'S, 49°11'–9°15'E). After its initial discovery (holotype MNHN 1937–19), the species was not found again until recently, when it was reported from campsites 2 and 3 in Marojejy (NE Madagascar) (Raselimanana et al. 2000. Fieldiana:Zoology, n.s. 97:157–174). During a series of surveys in this area the species was found in two additional localities as above, of which Ambolokopatrika is a mid-altitude rainforest between Marojejy and Anjanaharibe-Sud massifs (Andreone et al. 2000. Biodivers. Conserv. 9:1587–1622). The Masoala site is a low altitude rainforest corridor between two larger forest parcels. The specimens were captured using pitfalls. MRSN A2066 and A2115 measure 21.8 and 25.5 mm SVL, respectively, versus 26.1 mm in the holotype.

FIG. 1. *Plethodontohyla coudreaui* from Ambolokopatrika, NE Madagascar (MRSN A2066).

Submitted by **FRANCO ANDREONE,** Museo Regionale di Scienze Naturali di Torino, Via G. Giolitti, 36, I-10123 Torino, Italy; e-mail: f.andreone@libero.it.

PLEURODEMA GUAYAPAE (NCN). ARGENTINA. SAN LUIS: Sierra de las Quijadas National Park (32°20'–32°47'S, 67°10'–66°58'W). February and March 1999. J. C. Baldoni and A. C. Guerreiro. Herpetological Collection of the Universidad Nacional de San Luis, San Luis (UNSL–CH 0250 and 0252). Verified by Ismael di Tada. First province record. Previously reported from southeastern La Rioja; southern Catamarca, southwestern Santiago del Estero, and northwestern Córdoba (Barrio 1964. Physis XXIV[68]:471–489); the present record extends the known distribution 260 km S of Patquía, La Rioja, the type locality.

Submitted by **ANALIA GUERREIRO, JUAN CRUZ BALDONI,** and **ANA M. BRIGADA,** Universidad Nacional de San Luis. Facultad de Química, Bioquímica y Farmacia, Area de Zoología. Chacabuco y Pedernera, San Luis, (C.P. 5700), Argentina (e-mail: analiag@unsl.edu.ar).

PSEUDACRIS CRUCIFER (Spring Peeper). USA: ILLINOIS: MASON CO: 0.5 mi. N of 1370 N on 1900 E. 15 May 2002. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. Illinois Natural History Survey (INHS 18098). New county record. One male collected from a roadside ditch.

Submitted by **JOHN A. CRAWFORD**, Division of Biological Sciences, University of Missouri, Columbia, Missouri 65211, USA (e-mail: jac7vc@mizzou.edu), and **MATHYS J. MEYER,** Department of Biological Sciences, Illinois State University, Normal, Illinois 61790, USA (e-mail: altboer@hotmail.com).

PSEUDACRIS NIGRITA NIGRITA (Southern Chorus Frog). USA: VIRGINIA: YORK CO.: powerline right-of-way ca. 0.7 km

SE junction of Virginia Route 105 and Richneck Road (N 37.17791 W 76.50072). 3–5 April 2003. Emily C. Moriarty, Christopher S. Hobson, and Erikka Conrad. Verified by David Cannatella. Texas Memorial Museum (TMM 62399–62401). Adults were heard calling on three consecutive nights along a powerline that straddles Richneck Road, and lies along the southern edge of the Grafton Ponds Natural Area Preserve. Three specimens were collected during the period of 3–5 April. First record for Virginia (Mitchell and Reay 1999. Atlas of Amphibians and Reptiles in Virginia. Spec. Publ. No. 1, Virginia Department of Game and Inland Fisheries, Richmond, Virginia. 122 pp.; Tobey 1985. Virginia's Amphibians and Reptiles: A Distributional Survey, Virginia Herpetological Survey, Purcellville, Virginia, 113 pp.), and northernmost known locality. The North Carolina State Museum of Natural Sciences collection contains specimens from the nearest known *P. nigrita* populations in Beaufort Co., North Carolina (A. Braswell, pers. comm.), which is ca. 200 km S of the Virginia locality. Published range maps show the northern limits of distribution in east-central North Carolina (Conant and Collins. 1998. Reptiles and Amphibians of Eastern/Central North America. Houghton Mifflin Co., Boston, Massachusetts, 616 pp.; Martof et al. 1980. Amphibians and Reptiles of the Carolinas and Virginia. The University of North Carolina Press, Chapel Hill, 264 pp.). Other species calling at this site included *Pseudacris feriarum*, *P. crucifer*, *Hyla chrysoscelis*, *Rana sphenocephala*, and *Bufo fowleri*. Surveys conducted on 12 and 14 April 2003 along County Route 625 in Prince George County, Virginia revealed the presence of two choruses of *P. nigrita nigrita*, along with *P. brimleyi*, *P. crucifer*, *Bufo americanus*, *Acris gryllus*, and *Rana sphenocephala*. The Prince George County site is ca. 55 km W of the York County site.

Submitted by **CHRISTOPHER S. HOBSON,** Virginia Department of Conservation and Recreation, Division of Natural Heritage, 217 Governor Street, Richmond, Virginia 23219, USA (e-mail: cshobson@dcr.state.va.us), and **EMILY C. MORIARTY,** Patterson Laboratory 141, 24th and Speedway, University of Texas, Austin, Texas 78712, USA (e-mail: chorusfrog@mail.utexas.edu).

PTYCHADENA TRINODIS (NCN). MAURITANIA: Guelta Oumm Lebare (Wilaya Assaba), 16°29.472'N, 10°49.822'W. 31 May 2002. Museo Nacional de Ciencias Naturales, MNCN 41783. Verified by Ignacio de la Riva. Adult male was found active during the night near a pond. The area is a gorge with permanent water, belonging to the Sahel Savannah. Other amphibians noted were *Bufo xeros*, *Hoplobatrachus occipitalis*, and *Tomoptera cryptotis*. First record of this genus for Mauritania.

Submitted by **JOSÉ M. PADIAL**, Museo de Historia Natural Noel Kempff Mercado, Área de Zoología, Sección Herpetología, PO Box 2489, Santa Cruz de la Sierra, Bolivia; e-mail: jmpadial@yahoo.com.

SYNAPTURANUS SALSERI (Sapito apuntado de Salser). VENEZUELA: AMAZONAS: Tobogán de La Selva, 34 km S of Puerto Ayacucho (5°23'50"N – 67°37'04"W), 120 m elev. December 2002. Osvaldo Villareal. Museo de Historia Natural La Salle, Caracas, (MHNLS 15910–11). An adult and a juvenile found inside a decaying log. Verified by José Ayarzagüena. This species has been reported from Vaupés in Colombia (Pyburn 1975. Herpetologica 31:439–443; Ruiz Carranza et al. 1996. Rev. Acad. Colomb. Cienc. 20[77]:365–415) and near Neblina Base Camp on Baria River, Amazonas State, in Venezuela (Zweifel 1986. Amer. Mus. Novitates 2863:1–24; McDiarmid and Paolillo 1988. *In* Brewer Carias [ed.], Cerro Neblina. Resultados de la Expedición 1983–1987, pp. 667–670. Fudeci). Second record from Venezuela, and extends known range more than 350 km N from the previous records.

Submitted by **J. CELSA SEÑARIS, CESAR MOLINA**, and **OSVALDO VILLAREAL,** Museo de Historia Natural La Salle, Apartado 1930, Caracas 1010-A, Venezuela; e-mail: celsa35@hotmail.com.

TESTUDINES

APALONE SPINIFERA (Spiny Softshell). USA: MISSOURI: Crawford Co: Keysville, 4.0 km S–0.4 km E Crooked Creek crossing on county road (37°50'20"N, 91°23'05"W. 16 May 1965. M. P. McKelvey. Verified by R. W. Axtell. SIUE 454. New county record.

Submitted by **CAROL A. BRYANT**, 7841 S. Panther Creek Road, Mount Olive, Illinois 62069, USA; e-mail: cabryant@ctnet.net.

APALONE SPINIFERA (Spiny Softshell). USA: ILLINOIS: McLean Co: Bray Creek, a headwater of the Mackinaw River (40°32.35'N, 88°37.34'W). A juvenile was found on 8 August 2002. Mary H. Lee. Verified by John Petzing. Illinois Natural History Survey (INHS 18523). New county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8. Champaign, Illinois. 300 pp.).

Submitted by **MARY H. LEE**, Department of Biological Sciences, Illinois State University, Normal, Illinois 61790-4120, USA; e-mail: mhlee@ilstu.edu.

CLEMMYS (=GLYPTEMYS) MUHLENBERGII (Bog Turtle). USA: NORTH CAROLINA: Burke Co.: Recently dead specimen from natural senescence or predator related causes, 8.2 km airline NNE Morganton in an alder/shrub wetland. 6 October 2002. Eric Chapell and David Campbell. North Carolina Museum of Natural Sciences (NCSM 64264). Verified by Alvin L. Braswell. First county record. Fills a gap in the distribution and extends the range 38.2 km airline NE nearest Piedmont Province record in McDowell Co. (Herman et al. 1993. Herpetol. Rev. 24:154; Project Bog Turtle database) and 30.7 km airline SSE nearest Blue Ridge Mountain Province record in Avery Co. (Palmer and Braswell 1995. Reptiles of North Carolina. Univ. North Carolina Press, Chapel Hill; Project Bog Turtle database).

Submitted by **DENNIS W. HERMAN**, Project Bog Turtle, North Carolina Museum of Natural Sciences, 11 West Jones Street, Raleigh, North Carolina 27601-1029, USA, **DAVID CAMPBELL**, 430 9th Street NW, Hickory, North Carolina 28601, USA, and **ERIC CHAPELL**, Freedom High School, 511 Independence Boulevard, Morganton, North Carolina 28655, USA.

EMYDOIDEA BLANDINGII (Blanding's Turtle). USA: ILLINOIS: Mason Co: 0.5 mi. N of 1370 N on 1900 E. 24 May 2002. M. J. Meyer and J. A. Crawford. Verified by C. A. Phillips. Photographic voucher deposited at the Illinois Natural History

Survey (INHS 2002.04). Updates the last known specimen (INHS 7384) seen in 1954. One adult female was found in a roadside ditch.

Submitted by **JOHN A. CRAWFORD,** Division of Biological Sciences, University of Missouri, Columbia, Missouri 65211, USA (e-mail: jac7vc@mizzou.edu), and **MATHYS J. MEYER,** Department of Biological Sciences, Illinois State University, Normal, Illinois 61790, USA (e-mail: altboer@hotmail.com).

GRAPTEMYS PSEUDOGEOGRAPHICA KOHNII (Mississippi Map Turtle). USA: TEXAS: Bell Co: Fort Hood Military Reservation, arroyo near Belton Lake, 390 m NE of Taylor Valley Rd. (NAD 83 UTM Zone 14: N3450204m E636878m). 4 June 2002. Steven J. Taylor, Christopher A. Phillips, Jen Mui, and Jean K. Krejca. Verified by John E. Petzing. Illinois Natural History Survey (INHS 18234). New county record, extends range one county to southwest (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Univ. Press, College Station. 421 pp.). Shell of dead female with decomposing eggs and bones.

Submitted by **STEVEN J. TAYLOR, CHRISTOPHER A. PHILLIPS**, Illinois Natural History Survey, Champaign, Illinois 61820, USA, and **MICHAEL L. DENIGHT**, U.S. Army Engineer Research and Development Center, Champaign, Illinois 61826, USA.

PSEUDEMYS CONCINNA CONCINNA (Eastern River Cooter). USA: NORTH CAROLINA: Burke Co.: 8.2 km airline NNE Morganton, DOR. 13 October 2002. Eric Chapell and Patrick Heavner. North Carolina Museum of Natural Sciences (NCSM 64047). Verified by Alvin L. Braswell. First county record. First Catawba River system record. Extends the range 71.7 km airline NE nearest Broad River system record in Polk Co. and 111.5 km airline WSW nearest Yadkin River system record in Davie Co. (Palmer and Braswell 1995. Reptiles of North Carolina. Univ. North Carolina Press, Chapel Hill).

Submitted by **DENNIS W. LACERTILIA

ANOLIS PUNCTATUS. VENEZUELA: ESTADO BOLÍVAR: Gallery forest at Purumai River, SW Auyán-tepui, ca. 200 m from expedition base camp (05°54'33"N, 62°44'41"W), 420 m elev. 6 May 2002. C. Molina. Museo de Historia Natural La Salle, Caracas (MHNLS 15585). Quebrada Ataperé, headwaters of the Cucurital river, slopes of the Auyán–tepui (05°43'17.7"N, 62°34'21.1"W), 970 m elev. 5 November 2002. V. Romero and C. Molina. (MHNLS 16032). All verified by G. Rivas. The presence of this lizard in Venezuela was questionable. Previously it was believed to inhabit Amazona state (Donoso-Barros 1968. Carib. J. Sci. 8[3–4]:105–122), based on Boulenger (1885. Catalogue of the Lizards in the British Museum of Natural History. 2:xiii + 497 pp.) and other authors (Peters and Donoso-Barros 1970. Catalogue of the Neotropical Squamata: Part II. Lizards and Amphisbaenians. U.S. Natl. Bull., 297:64; La Marca 1997. Vertebrados Actuales y Fósiles de Venezuela. Serie Catálogo Zoológico de Venezuela. Vol. 1. Museo de Ciencia y Tecnología de Mérida, Venezuela). However, Avila-Pires (1995. Lizards of Brasilian Amazonia [Reptilia:Squamata], Zool. Verh. Leiden 299:1–706) had already indicated that the Donoso-Barros (1968, *op. cit.*) record for Territorio Amazonas was questionable because Boulenger (*op. cit.*) did not cite any specimen from Venezuela. Given the evidence, MHNLS specimens constitute the first museum vouchers for this species in the country. The single specimen extends the range for the species more than 450 km W of the nearest reported locality, close to the confluence of the Cuyuní and Essequibo rivers, in Guyana and more than 300 km NE of a doubtful record in Serra Parima, Roraima, Brazil (Avila-Pires, *op. cit.*: 97, map 26).

Submitted by **CÉSAR MOLINA**, **CELSA SEÑARIS**, Museo de Historia Natural La Salle, Sección de Herpetología, Apartado Postal 1930, Caracas 1010-A, Venezuela (e-mail: washaema@hotmail.con and celsa35@hotmail.com, respectively), and **ENRIQUE LA MARCA** Laboratorio de Biogeografía, Universidad de Los Andes, Mérida, Venezuela (e-mail: lamarca1@telcel.net.ve).

ANOLIS SAGREI (Brown Anole). USA: ARKANSAS: Pike Co: 3.7 km SW Langley off AR 84, Little Missouri River watershed. 20 October 2002. C. S. Harris. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 27317). Verified by Malcolm L. McCallum. First specimen reported from Arkansas (Trauth et al., Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville, *in press*), a non-gravid adult female (SVL = 46 mm). This common invader is known to use hitchhiking (primarily in nursery plants from Florida), and has been reported in neighboring Texas (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Univ. Press, College Station. 421 pp.) and Louisiana (T. S. Campbell, pers. comm.).

EUMECES LATICEPS (Broad-headed Skink). USA: ILLINOIS: MACOUPIN CO: 3.4 km ENE of Benld and N of Mount Olive Lake (39°06'23"N, 89°45'35"W). 1 August 2001. C. A. Bryant. Verified by R. W. Axtell. SIUE 2829. New county record.

Submitted by **CAROL A. BRYANT**, 7841 South Panther Creek Road, Mount Olive, Illinois 62069, USA; e-mail:cabryant@ctnet.net.

HEMIDACTYLUS GARNOTII (Indo-Pacific Gecko). USA: FLORIDA: DESOTO CO: Arcadia, 1173 SW Highway 17, was Don Olson Tires now Tires Plus (27.2350°N, 81.8526°W). 8 July 2001. Florida Museum of Natural History (UF131763). Collected by Gregg S. Klowden. Verified by Kenneth L. Krysko. New county record. This species has been reported from neighboring counties and many others throughout peninsular Florida (Conant and Collins 1991. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. Houghton Mifflin Co., Boston, Massachusetts, 450 pp.; Meshaka 1997, Florida Scientist 60:1–7).

Submitted by **GREGG S. KLOWDEN**, University of Florida, Department of Wildlife Ecology and Conservation, Gainesville, Florida 32611–0430, USA; e-mail: snakeman@ufl.edu.

LIOLAEMUS ALTISSIMUS ARAUCANIENSIS (NCN). CHILE: IX REGION DE LOS LAGOS: Provincia de Malleco, Malalcahuello (38°26'29"S, 71°31'25"W), 30 km E of Curacautín. 22 November 2000. D. Pincheira–Donoso. Herpetological Collection Museo Nacional de Historia Natural de Chile (MNHN 3474). Verified by H. Núñez. *Liolaemus altissimus araucaniensis* has been known from Villarrica Volcano, Cautín Province (Veloso and Navarro 1988. Boll. Mus. Reg. Sci. Nat. Torino 6:481–539). This specimen was found associated with the *Araucaria araucana* forest, and represents the first record from Malleco Province. This report extends the known distribution of the species ca. 115 km N from previously known localities.

Submitted by **DANIEL PINCHEIRA-DONOSO**, Sección Zoología, Museo Nacional de Historia Natural, Casilla 787, Santiago, Chile; e-mail: dpinchei@udec.cl.

LIOLAEMUS JAMESI (James' Jararanco). CHILE: I REGION DE TARAPACÁ: Quebrada Copaquiri (20°55'S, 68°52'W). 24 February 1994. Herman Núñez. Herpetological Collection Museo Nacional de Historia Natural, Santiago, Chile (MNHN–2612–14). Verified by Herman Núñez. *Liolaemus jamesi* has been known from Tarapacá Andean regions (Donoso-Barros 1966. Reptiles de Chile, Eds. Universidad de Chile) and Chungará (Núñez 1992. Smithson. Herpetol. Info. Serv. 91:1–29 ; Veloso et al. 1982. Sínt. Proy. MAB–6–UNEP-UNESCO–1105–77–01. La vegetación y los vertebrados inferiores de los pisos altitudinales entre Arica y el Lago Chungará, vol. I:135–268). All specimens found at 3850 m elev. Extends the known distribution of this species ca. 290 km S from previously known localities.

Submitted by **DANIEL PINCHEIRA-DONOSO** and **CARLOS GARÍN,** Sección Zoología, Museo Nacional de Historia Natural, Casilla 787, Santiago, Chile.

LIOLAEMUS YANALCU (NCN). ARGENTINA: SALTA-JUJUY. National Road N°40, on the boundary between provinces of Salta and Jujuy, at 36 km S of intersection of national roads n°52 and n°40. 18 January 2003. Museo de Ciencias Naturales, Universidad Nacional de Salta, Salta (MCN 939). F. Lobo and S. Lobo. Verified by J. M. Díaz Gómez. This species, recently described (Martínez Oliver and Lobo 2002. Cuad. Herpetol. 16:47–64) was known only from the Nevado del Acay area 50–60 km S of this location.

Submitted by **FERNANDO LOBO** and **SANTIAGO LOBO**, Cátedra de Anatomía Comparada, Fac. de Cs. Naturales, Universidad Nacional de Salta. Avda. Bolivia 5150, 4400-Salta, Argentina; e–mail: flobo@unsa.edu.ar.

NACTUS PELAGICUS (Rock Gecko). USA: COMMONWEALTH OF THE NORTHERN MARIANA ISLANDS: ANATAHAN: 16°21'18"N, 14°54'30.8"E. 27 April 2002. Nathaniel Hawley. Verified by Steve W. Gotte. National Museum of Natural History (USNM 550136, 550137). New island record. Collected in rotten *Neisosperma oppositifolia.*

Submitted by **NATHANIEL HAWLEY,** Commonwealth of the Northern Mariana Islands, Department of Lands and Natural Resources, Division of Fish and Wildlife, PO Box 10007, Lower Base, Saipan, MP 96950, USA; e–mail: boigaman@itecnmi.com.

SCELOPORUS UNDULATUS (Eastern Fence Lizard). USA: FLORIDA: MANATEE CO: 17 km E of Parrish, at Florida Park Service Parcel - Beker A (South Fork), N of State Road 62; T33S;

R21E; Sec. 18. 30 May 2002. C. R. Becker. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 135175). New county record and extends the range south and west of known distribution in Florida.

Submitted by **CHRISTOPHER R. BECKER,** Florida Park Service, District 4 Administration, Osprey, Florida 34229, USA; e-mail:chris.becker@dep.state.fl.us.

SCINCELLA LATERALIS (Ground Skink). USA: MISSOURI: MADISON Co: 3.2 km W of Bollinger Co. line on Missouri 72 at the Castor River crossing (37°31'45"N, 90°10'20"W). 1 May 1971. J. Puricelli. Verified by R. W. Axtell. SIUE 2538. New county record.

Submitted by **CAROL A. BRYANT,** 7841 South Panther Creek Road, Mount Olive, Illinois 62069, USA; e-mail: cabryant@ctnet.net.

SERPENTES

BOTHRIOPSIS TAENIATA or ***BOTHROPS TAENIATUS*** (Speckled Forest-pitviper). ECUADOR: PROVINCIA DE ZAMORA-CHINCHIPE: Zamora (ca. 4°05'S, 78°55'W; 900–1200 m elev.). Two specimens; 26 May 1999, Colón Reyes; July 1999, Hector Apolo. Instituto Nacional de Higiene y Medicina Tropical (INHMT 4018 and 4062, respectively). Verified by Luis A. Coloma. This species has a wide distribution in South America E of the Andes (Campbell and Lamar 1989. The Venomous Reptiles of Latin America. Comstock/Cornell University Press, Ithaca, New York. 425 pp.) and has previously been recorded from the Ecuadorian provinces of Napo, Pastaza, and Morona–Santiago (Pérez-Santos and Moreno 1991. Mus. Reg. Sci. Nat. Monogr. 11:1–538). This is the first record for the adjacent province of Zamora-Chinchipe and documents the occurrence of this species in the upper Río Zamora valley, which is separated from Amazonian lowlands by the mountain ranges of the Cordillera de Tzunantza and the Cordillera del Condor. On the Amazonian (Peruvian) versant of the Cordillera del Condor, this species has been collected at the upper Río Comainas (Reynolds and Icochea 1997. RAP Working Papers 7:82–90+204–206). As the generic assignment of this pitviper species is controversial, we offer the two most widely recognized combinations to facilitate information retrieval.

Submitted by **ANTONIO FREIRE L.** and **FERNANDO GARCIA**, Departamento Ofídios, Instituto Nacional de Higiene y Medicina Tropical "Leopoldo Izquiéta Pérez," Casilla 3961, Guayaquil, Ecuador, **WOLFGANG WÜSTER**, School of Biological Sciences, University of Wales Bangor, Bangor, Gwynedd LL57 2UW, United Kingdom, and **ULRICH KUCH**, Sektion Herpetologie, Forschungsinstitut und Naturmuseum Senckenberg, Senckenberganlage 25, 60325 Frankfurt am Main, Germany; e-mail: U.Kuch@em.uni-frankfurt.de.

CARPHOPHIS AMOENUS (Worm Snake). USA: ILLINOIS: MASSAC Co: CR1775N, 16 S 0334738E 4133283N (WGS 84). 28 April 2002. M. J. Ingrasci and C. Mock. Illinois Natural History Survey (2002.25). Verified by C. A. Phillips. This locality constitutes a new county record (Phillips et al. 1999. Illinois Nat. Hist. Surv. Man. 8:1–282).

Submitted by **MATTHEW J. INGRASCI**, Department of Biological Sciences, University of Notre Dame, Notre Dame, Indiana 46556-0369, USA; e-mail: mingrasc@nd.edu.

CEMOPHORA COCCINEA (Scarletsnake). USA. TENNESSEE: RUTHERFORD Co.: Hwy 70S at Cripple Creek Rd. crossing. DOR 5 Aug 1994. B. T. Miller, J. L. Miller. Verified by V. Cobb. Middle Tennessee State University (MTSU 88S). County record.

Submitted by **BRIAN T. MILLER** and **JOYCE L. MILLER**, Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee 37132, USA; e-mail: bmiller@mtsu.edu.

CROTALUS MITCHELLII PYRRHUS (Southwestern Speckled Rattlesnake). USA: ARIZONA: COCONINO Co: Colorado River: Havasu Canyon, river mile (RM) 156.8 L: 1.6 km from the Colorado River, 36.30°N, 122.75°W. June 1999. Nikolle L. Brown. KU–CT 11898. Verified by Eric M. Rundquist. First verified record in the Grand Canyon region. There are also additional records from Havasu Canyon: June 1999, KU–CT 11899–11900; and GRCA 32949 from S of Mooney Falls, 2.2 km from the confluence of the Colorado River (initially misidentified, John Weinschenk, 1969).

Crotalus mitchellii was never mentioned by Miller et al. (1982. Amphibians and Reptiles of the Grand Canyon. Grand Canyon Nat. Hist. Assoc., Grand Canyon, 143 pp.). Lowe et al. (1986. The Venomous Reptiles of Arizona. Arizona Game and Fish Dept, Phoenix, 115 pp.) state "its distribution within the Grand Canyon remains poorly known." Stevens (1993. The Colorado River in Grand Canyon: a Guide, 5th edition, Red Lake Books, Flagstaff, Arizona, 115 pp.) mentions this species is rare in lower end of the canyon. However, there have been no records published of this species inhabiting the Grand Canyon. Based on my experience with visitors in the canyon, *C. mitchellii* has been frequently misidentified as *C. abyssus*, the Grand Canyon rattlesnake.

These are the upstream-most voucher specimens of *Crotalus mitchellii* in the Grand Canyon. As of April 2003, the furthest downstream record of *C. abyssus* in the canyon is from Fern Glen, RM 168 (KU-CT 11901), indicating an overlap of ca. 11.2 river miles (17.92 km) for these two species in the Grand Canyon.

Submitted by **NIKOLLE L. BROWN**, 7779 North Leonard, Clovis, California 93611, USA; e-mail: black-catnik@att.net.

CROTALUS SCUTULATUS (Mojave Rattlesnake). USA: ARIZONA: MOHAVE Co: Hualapai Indian Reservation, Quartermaster Point, 0.8 km from the Colorado River: river mile (RM) 260.5 L: 35°58'N, 113°47'W. Summer 1999. Ralph Jones. KU CT 11885. Verified by Cecil R. Schwalbe. First verified record in the Grand Canyon Region. Miller et al. (1982. Amphibians and Reptiles of the Grand Canyon. Publ. Grand Canyon Natural History Association. 114 pp.) suggested that it was probable that *C. scutulatus* might inhabit the lower end of the canyon, however there were no confirmed records. Grater (1981. Snakes, Lizards, and Turtles of the Lake Mead Region. Publ. Southwest Parks and Monuments Association. 47 pp.) mentioned that *C. scutulatus* did not appear common in the Lake Mead Region. Lowe et al. (1986. The Venomous Reptiles of Arizona. Publ. Arizona Game and Fish Department, Phoenix. 115 pp.) show the northern distribution of *C. scutulatus* extending north close to the Colorado River near Peach Springs Canyon (RM 225.7 L) and reaching the Colorado River at Pierce Ferry (RM 280 L), but not found near the Colorado River in the region in between.

Submitted by **NIKOLLE L. BROWN**, 7779 North Leonard, Clovis, California 93611, USA; e-mail: black-catnik@att.net.

CROTALUS TIGRIS (Tiger Rattlesnake). USA: ARIZONA, MARICOPA CO: Buckeye Hills, Hassayampa SE 1/4 sec. UTM 3683.40N, 338.75E, ca. 1.6 km E Gila River, 2.8 km S Powers Butte. 4 September 1999. R. D. Babb. Verified by C. R. Schwalbe. UAZ 52169. Represents W extension of distribution ca. 32 km in N reaches of U.S. distribution (Lowe et. al. 1986. Venomous Reptiles of Arizona. Arizona Game and Fish Department, Phoenix. 115 pp.). At this latitude *Crotalus trigris* is strongly associated with Arizona Upland communities. The vegetation of the Buckeye Hills is Lower Colorado subdivision, typical of the more xeric habitat that dominates western Arizona lowlands.

DENDRELAPHIS STRIATUS (Cohn's Bronzeback). WEST MALAYSIA: PAHANG: Pulau Tioman: Kampung Juara (2°47.73'N; 104°12.26'E). 18 July 2002. Perry L. Wood, Danny Morgan, and Jesse L. Grismer. Female, 504 mm SVL, 764 mm TL. Zoological Reference Collection, The National University of Singapore, Singapore (ZRC) 2.5539. Verified by L. Lee Grismer. New island record. Previously known from southern Thailand, west Malaysia, Borneo, and south to Sumatra and Pulau Nias (Manthey and Grossman 1997. Amphibien und Südostasiens. Natur und Tier-Verlag, Münster. 339 pp.). The specimen was collected on a medium-sized coconut palm (ca. 0.5 m diam), ca. 1 m above the ground at 1200 h in the coastal vegetation. This individual was sighted while basking on the side of the tree.

Submitted by **PERRY L. WOOD**, **NURUL'AIN ELIAS**, and **DANNY MORGAN**, Department of Biology, La Sierra University, Riverside, California 92515-8247, USA; e-mail: perrwood@lasierra.edu.

DRYOCALAMUS GRACILIS (Scarce Bridal Snake). SRI LANKA: NORTHERN CENTRAL PROVINCE: Kurunegala District, Ambanpola (07°55'N, 80°13'E). 18 March 2002. Colombo National Museum (CMS2003–2–1). Male hit by a motor vehicle on the road. Verified by K. Manamendra-Arachchi. *Dryocalamus gracilis* is a very rare species, distinguishable from its relative *D. nympha* by the presence of 15 scale rows at midbody (13 in *D. nympha*) and anal plate usually entire (divided in *D. nympha*) (de Silva 1980. Spolia Zeylanica 34:263–266). Mahendra (1984. Ann. Zool. 22:211) considered *D. gracilis* conspecific with *D. nympha*, despite the differences noted above, an opinion not accepted by all subsequent authors (de Silva 1990. Colour Guide to the Snakes of Sri Lanka. R & A Publishing; Das 1996. Biogeography of the Reptiles of South Asia. Krieger Publ., Malabar, Florida). *Dryocalamus gracilis* is reported from Peninsular India (as far north as Orissa) and from False Island, off the Rakhine (Arakan) coast of Myanmar. For Sri Lanka it is known from only two specimens collected from the Jaffna Peninsula, in the extreme north, and recorded as *Odontomus fergusoni* (Haly 1888. Taprobanian III p. 51). The present report represents only the third specimen of *D. gracilis* for Sri Lanka, the first for 114 years, and the southernmost record of the species with a range extension of at least 196 km from Jaffna. We thank YAP Films and Animal Planet for funding and support of the project "O'Shea's Big Adventure Series 3: Venom" in Sri Lanka.

Submitted by **MARK O'SHEA**, School of Applied Sciences, University of Wolverhampton, Wolverhampton, WV1 1SB, England (e-mail: oshea@snakemos.demon.co.uk), and **ANSLEM DE SILVA**, Faculty of Medicine, University of Peradeniya, Peradeniya, Sri Lanka (e-mail: kalds@sltnet.lk).

ELAPHE GUTTATA GUTTATA (Corn Snake). USA: US VIRGIN ISLANDS: St. Thomas: Crown Bay Cargo Port Area (18°20.29'N, 64°56.84'W). 3 October 1999 and two undated specimens from the 1990s. Judy Pierce and Donna Griffin. Both specimens verified by Jose Rosado. The dated specimen, an adult female, 66 cm SVL, 80 cm TL, was found at the industrial park near Victor's Hideout restaurant, ca. 600 m W of the Crown Bay cargo port area. It is preserved in the collection of the US Virgin Islands Division of Fish and Wildlife (address below). The two undated specimens are at the Museum of Comparative Zoology. MCZ 183544 is an adult male, SVL 83 cm, TL 103 cm; MCZ 183545 is a juvenile, SVL 31 cm, TL 37 cm.

Circumstantial evidence suggests these specimens might have arrived in cargo containers originating in Florida, a pattern which is consistent with other reports of introduced reptiles and amphibians in the Caribbean (e.g., Powell 2002. Herpetol. Rev. 33:321). Repeated sightings, as well as the capture of juveniles at the site, suggest a nascent population might be in the process of emerging. This is a first documented record for this part of the Caribbean. Previous published records include Antigua (Powell and Henderson 2003. Herpetol. Rev., *in press*), Anguilla (Hodge et al. 2003. The Reptiles and Amphibians of Anguilla, British West Indies. Anguilla National Trust, The Valley), and St. Barts (Breuil 2002. Patrimones Naturels 54:1–339). In addition, although no specimens are available, corn snakes have also been reported from Curaçao and Bonaire. These too might have arrived from Florida, and juveniles have been reported on Curaçao as well (Gerard van Buurt, unpubl. obs.). If the presence of juveniles indicates local reproduction, this is a source of conservation concern because, similar to the invasive brown treesnake (*Boiga irregularis*; Rodda et al. 1999. Problem Snake Management: the Habu and the Brown Treesnake. Cornell University Press, Ithaca, New York. 534 pp.), *E. g. guttata* has a generalized vertebrate diet. What effect the presence of introduced Indian mongooses in St. Thomas (Horst et al. 2001. *In* Woods and Sergile [eds.], Biogeography of the West Indies: Patterns and Perspectives, pp. 409–424. CRC Press, Boca Raton, Florida) might have on the future and impact of the species remains to be seen.

We thank Kate LeVering and Robert Henderson for critically reading the manuscript. Financial support was provided by The Conservation Agency through a grant from the Falconwood Foundation. This is manuscript T–9–973 of the College of Agricultural Sciences and Natural Resources, Texas Tech University.

Herpetological Review, 2003, 34(3), 266–269.

New Herpetofaunal Records for Psara and Neighboring Islands, Aegean Sea, Greece

GEORGE SIDERIS*
and
ANNE DUPERAULT
Long Island University, Biology Department
1 University Plaza, Brooklyn, New York 11201, USA

**Corresponding author; e-mail: Gsideris@LIU.edu*

Psara and its neighboring islands are a poorly studied cluster of Greek islands in the northeastern part of the Aegean Sea. Few herpetofaunal surveys have been conducted for these islands. Psara lies 150 km east of Athens and about 25 km west of Turkey's eastern coast (Fig. 1), in an area known as the Anatolian-European transition zone (Legakis et al. 1999) because it represents a convergence zone for species representative of Europe and Asia Minor. This report is the first intensive herpetological survey for the Psara archipelago. Previous surveys (e.g., Tsunis and Dimitropoulos 1994) of the surrounding Aegean islands made only passing reference to Psara. One early survey of the herpetofauna from many Aegean islands (Werner 1930) has no mention of Psara. In a checklist of Greek lizards, Chondropoulos (1986) does not list *Cyrtopodion kotschyi*, *Hemidactylus turcicus*, or *Ablepharus kitaibelii* for Psara but has a subspecies of *Ophisops elegans* as present.

The neighboring islands of Chios and Lesvos receive 600–800 mm of rainfall annually (Tsunis and Dimitropoulos 1994) with Psara getting less and often no rainfall during the summer months. The temperatures on Psara range from 5°C during the winter to 40°C in the summer. Psara has an area of ca. 43 km^2 and sustains a small population of about 500 people that is doubled during the summer months. There is a small village (labeled in Fig. 1) and a military base in the southern peninsula. Cultivation is rare and localized to the southern region while the northern part of the island is mostly uninhabited. Few roads exist, with one main road connecting the village, monastery, and a radio tower that lies in the northern area of the island. The terrain consists of garrigue to low maquis vegetation with *Sarcopoterium spinosum* as the domi-

nant species in undisturbed areas and *Genista acanthoclada* as the dominant species in abandoned fields. A floristic analysis (Greuter 1976) indicates that Psara was probably isolated from the neighboring islands and did not share a land connection during the lowered sea level of the last ice age. Psara's flora apparently shares a relationship to the western Aegean islands rather than to those to its east.

The island is fairly mountainous with the highest peak reaching 531 m. Damage from overgrazing, occasional fire, and human activity is widespread on Psara. There are four major uninhabited islets near Psara: Agios Nikolaos, Daskalio, Mastroghiorghi, and Prasonisi. Prasonisi lies about 62 m off the north coast of Psara and Mastroghiorghi is 65 m off the NW coast. These two islets are nesting sites for *Falco eleonorae* (Eleonora's falcon). Agios Nikolaos lies 300 m off the western coast of Psara. A small church is located on Agios Nikoloaos, but visits to the island are rare. Daskalio is uninhabited and is ca. 110 m W of Psara.

Antipsara, located 2 km W of Psara, is uninhabited. There is a small sheepfold by the southeastern shore that is occasionally used as a temporary shelter by the local fishermen throughout the year. There are two islets south of Antipsara: Kato Nisi and Meso Nisi. Antipsara and Kato Nisi have a garrigue to low maquis vegetation similar to that of Psara but Meso Nisi has a strikingly different vegetation, several succulents and leafy plants being ungrazed. Antipsara receives little human disturbance throughout the year.

Of the larger Aegean islands, the closest to Psara is Chios, ca. 18 km eastward. The other islands are farther away: Skyros is over 76 km to the west, Lesvos lies 38 km to the northeast, and finally Samos is 55 km to the southeast of Psara.

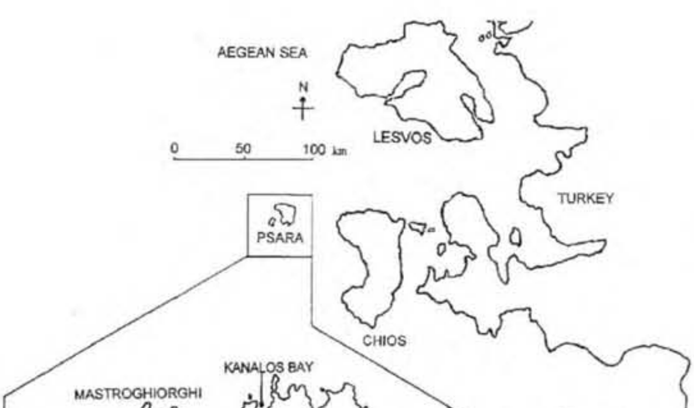

FIG. 1. Composite map showing region in Psara vicinity (modified from a map in a tourist publication), and detail map of Psara redrawn after Greuter (1976).

Our fieldwork was conducted during three seasonal visits from mid-June to July, 2000–2002. The goal was to survey the island's herpetofauna and see what future studies should be conducted. Specimens were captured by hand, pitfall, and glue traps. All collected specimens were deposited at the Long Island University (Brooklyn Campus) Vertebrate Collection (LIUZOO). There are new records of *Ablepharus kitaibelii* and *Bufo viridis* for Psara. A comparison with the herpetofauna of Chios, Lesvos, and Samos is presented.

Anura

Bufo viridis (Green Toad). Limnos, Psara. 19 June 2002. G. Sideris. LIUZOO 19–21. This toad is known to tolerate harsh environments—surviving in xeric conditions (Bringsøe 1985; Clark 1989). No amphibians were seen during the 2000 and 2001 surveys and this was not surprising as the island is so arid. There were no indications of amphibian presence even at seasonal pools during the 2000 and 2001 survey and no published record for Psara. However, the islands had received unusually heavy rain during the winter and spring of 2002 as noted during fieldwork. As an explosive breeder *B. viridis* was able to populate the island with its offspring in spring 2002. Toads were so numerous around the island that some were crushed by pedestrians on a road. Tadpoles were found in almost every standing body of water throughout the island including one brackish pool. Similar observations regarding plentiful *B. viridis* populations—often after a heavy rain—have been made on other Aegean islands (Buttle 1989) although this species is still prone to human interference in water systems. The green toad population on Samos is quite widespread (Ioannides et al. 1994). Other records of *B. viridis* exist for Lesvos and Chios (Axiotis 1998; Ioannides et al. 1994). Tsunis and Dimitropoulos (1994) found *B. viridis* only on Lesvos and not on Chios. A brief visit to Psara in August 2002 failed to yield any specimens in spite of the continued presence of some water pools.

Testudines

Mauremys caspica (Striped-neck Terrapin). Xerokampo, Psara. 12 July 2000. G. Sideris. LIUZOO 016–018. The population is located along a 30 m stretch of a seasonal stream bed which flows to Kanalos Bay in the north, over a bed of conglomerate rock. No other localities on Psara, even those with seasonal pools, sustained individuals of *M. caspica*. These terrapins were found in three temporary pools of stagnant water and in a man-made cistern. These pools and the cistern are often too deep for *M. caspica* to climb out of and should the water dry up, which is very likely during late summer, death occurs due to overheating and dehydration. Three live turtles were found in such a desiccated pool. In the 2000 season, two dead turtles were collected from a dried-out cistern in the vicinity. All of the live turtles found were marked and released. Although this population of *M. caspica* seems marginal, juveniles were found in the 2002 field season. A thorough census of this small population is planned for 2003. Records of this terrapin have been noted for Chios and Lesvos (Tsunis and Dimitropoulos 1994) as well as for Samos (Ioannides et al. 1994).

Lacertilia

Cyrtopodion kotschyi (Kotschy's Gecko). Lazareta Bay (500 m E of the village), Psara. 18 June 2002. A. Duperault and G. Sideris.

Caught by glue trap on a sandy habitat, ca 50 m from beach area. LIUZOO 004. Agios Nikolaos. 28 June 2002. G. Sideris. Found under a piece of wood near the church. LIUZOO 13. *Cyrtopodion kotschyi* was found in most parts of Psara including the Agios Nikoloaos islet. This is the most widespread lizard in the Aegean (Tsunis and Dimitropoulos 1994; Valakos 1989), although there are few records for the larger northeastern islands (Tsunis and Dimitropoulos 1994). Although records exist on both Lesvos and Chios (Ioannides et al. 1994; Tsunis and Dimitropoulos 1994) it should be noted that the Chios record from the Tsunis and Dimitropoulos (1994) survey was found at Karfas beach under rotting wood—quite close to shore. This finding is interesting as we found this gecko to be quite common on Psara which is only 18 km W of Chios. An older survey (Werner 1930) cites this gecko as common in Skyros which lies 70 km WNW of Psara. Success of *C. kotschyi* on small islets has been noted previously, sometimes being the only reptile recorded (Clark 1989). This gecko was usually seen on buildings and stone walls and sometimes hidden in *Sarcopoterium spinosum* shrubs. It was easily found in the village but also in remote areas. During our visits, *C. kotschyi* was not observed at elevations above 300 m, and it was not found on Antipsara. Activity was primarily nocturnal but occasionally it was seen during the day, usually in the shade of stone walls.

Hemidactylus turcicus (Mediterranean Gecko). Psara. 27 June 2002. A. Duperault and G. Sideris. Caught by glue traps in an abandoned sheepfold, ca. 6.2 km N of the village (ca. 300 m elev.). LIUZOO 005–008. Antipsara. 22 June 2002. C. Matyi and A. Duperault. Found under a piece of wood near the sheepfold, ca 15 m from the southeastern coast. LIUZOO 015. This species was observed in all areas of Psara and Antipsara, and was most commonly found at an elevation of 300 m on Psara. We concur with previous observations that this gecko is nocturnal (Clark 1989). During the day we found *H. turcicus* hidden under rocks but one specimen was caught in a pitfall trap near a *S. spinosum* shrub. This gecko is common on Chios, both near human settlements and in fields (Tsunis and Dimitropoulos 1994). However, *H. turcicus* was not found to be as common in the village, and it was usually found in areas that received little human disturbance. Although *C. kotschyi* and *H. turcicus* occurred in the same area, *H. turcicus* was found in greater numbers in places where *C. kotschyi* was absent.

Ophisops elegans (Snake-eyed Lizard). Lazareta Bay, Psara. 19 June 2002. A. Duperault and G. Sideris. Collected at a sandy beach habitat, ca. 500 m from the village. LIUZOO 001–002. In village, Psara. 24 June 2002. G. Sideris. LIUZOO 010. Ftelio, Psara. 26 June 2002. George Sideris. Collected at a sandy habitat. LIUZOO 012. This lizard was found in most parts of Psara. Although *O. elegans* was found to be quite common on Psara by Tsunis and Dimitropoulos (1994), even at high altitudes, we observed a noticeable decrease at higher elevations. During the course of the study, *O. elegans* was found abundantly in lowland fields but also in mid-grade hills though less common. Only one lizard was seen and caught at an elevation of ca. 250 m, and none at higher elevations. There was a complete absence of *O. elegans* on Antipsara and its neighboring islets throughout the study periods.

Ablepharus kitaibelii (Snake-eyed Skink). Lazareta Bay, ca. 500 from the village, Psara. 18 June 2002. Anne Duperault. Collected at a sandy beach habitat. LIUZOO 003–014. Ca. 6.2 km N of the village (ca. 300 m elev.). 27 June 2002. Anne Duperault. Caught by a glue trap in an abandoned sheepfold. LIUZOO 009. Antipsara, ca. 40 m from seashore. 28 June 2002. Anne Duperault. Caught by hand. LIUZOO 011. This skink was ubiquitous throughout Psara and Antipsara. There was no indication that the population was restricted to the lowlands (Arnold and Burton 1978), as it was found at elevations of 300 m and higher. *Ablepharus kitaibelii* was most often found hidden in *S. spinosum* bushes. Adults were often secretive but juveniles were the only specimens observed on Psara that occasionally ventured into open patches only to run from one *S. spinosum* bush to another. In contrast, adults and juveniles on Antipsara were more evident in open spaces.

Discussion.—Chios, being much larger than Psara, supports a variety of habitats and populations of reptiles and amphibians (Chondropoulos 1986, 1989; Dimitropoulos 1990a; Ioannides et al. 1994; Tsunis and Dimitropoulos 1994). However, there is a limited record of *Cyrtopodion kotschyi* while this species is commonly found on Psara. There are no records of *Ablepharus kitaibelii* from Chios.

Unexpectedly, we found no snakes on Psara, despite its proximity to Chios, which supports eight species of snakes (Chondropoulos 1989; Dimitropoulos 1986, 1990a, 1990b; Ioannides et al. 1994; Tsunis and Dimitropoulos 1994). In fact, Chios is commonly referred to as "Snake Island." The absence of snakes on Psara (Tsunis and Dimitropoulos 1994) has created village legends such as one that tells of a priest's curse that lead to the disappearance of all the snakes from the island. Another bit of folklore is from those who believe that the island's soil is toxic to snakes. There is no geographical and/or toxicological explanation to suggest that snake populations could not have existed on the island.

Because of the presence of snakes in all of the surrounding islands, it would be expected that snakes must have existed on the island in the past. However, other small islands, such as Anafi and Astypalea, carry equal reputations of no snake populations and it might be the island's size and not the soil composition that results in their absence (Gruber 1979). However, some eastern Aegean snake species, notably *Eryx jaculus* and *Telescopus fallax*, have adapted to hot, dry conditions—typical of the islands in the Aegean (Gruber 1979). Thera, located in the Kyklades archipelago, is a much larger Aegean island that lacks amphibians and tortoises but has two snake species (Frör and Beutler 1978). This is of interest in terms of dispersal, as most likely the fauna on Thera was extirpated in a volcanic eruption over 3600 years ago (Gruber 1979).

Thus, further study is needed to explain the absence of snakes from Psara and Antipsara. One hypothesis is that the native snakes have been extirpated by humans as the island has been heavily populated for over 4000 years (Mycenaeans were living on the island in 2400 B.C.). Although tedious, a plan of sifting through some thick sedimentary deposits for reptile bones would be a useful test to this hypothesis.

Furthermore, there were village rumors of the existence of a legless lizard, most likely *Pseudopus apodus*. Despite our efforts we were unable to verify its presence but we cannot dismiss its existence on Psara as it is common on Lesvos (Axiotis 1998; Tsunis and Dimitropoulos 1994). We doubt that the village people are able to differentiate between a legless lizard and a snake. Thus,

although *P. apodus* might exist on Psara, it is conceivable that the rumor instead derives from the mistaken observation of a snake, as yet unrecorded by us, as the local people are proud of the island's reputation of being snakeless.

We recorded only *A. kitaibelii* and *H. turcicus* on Antipsara. The apparent absence of *O. elegans* and *C. kotschyi* from Antipsara is enigmatic, as Antipsara and Psara largely consist of the same habitat types, and *O. elegans, C. kotschyi, H. turcicus,* and *A. kitaibelii* have been found in the same habitat on Psara.

In light of the above there are some enigmas relating to ideas of species dispersal between the islands. Although the herpetofauna of the Psara archipelago is similar to that observed on smaller North Aegean islands, such as Aghios Efstratos (Schneider 1994), the new record of *A. kitaibelii* is significant not only in terms of its absence from Chios but also of its success on Psara and Antipsara. One factor contributing to the limited number of species recorded in our surveys is the lack of fresh water on Psara. This observation is consistent with a survey on Agios Efstratios, another small North Aegean island (Schneider 1994). A planned molecular study should elucidate population relationships between Psara and Chios. The survey described here has laid the groundwork for a long-term investigation of the Psara archipelago.

Acknowledgments.—We thank members of our field party for their collection efforts. Thanks are also addressed to a number of individuals who helped us with transport and equipment. Specimen identifications were confirmed by C. J. Raxworthy (American Museum of Natural History; all reptiles) and A. Dimitropoulos (Goulandris Natural History Museum, Kifissia, Greece; *Bufo viridis*). Additional acknowledgments are extended to E. Valakos and J. T. Collins for their assistance.

During the course of fieldwork, from March 1997 to April 2000, in the Calakmul Biosphere Reserve (17°45' and 19°15'N, 89°15' and 90°10'W) and surrounding areas of Campeche, México, we documented several new records for amphibian and reptile species that either represent significant range extensions on the Yucatán Peninsula or new records for the state of Campeche. Records are from the Municipality of Calakmul, mainly from the archaeological site of Calakmul (AS) (18°06'26"N, 89°48'34"W), unless indicated otherwise. The specimens were collected by the authors and deposited in the Herpetological Collection, Museo de Zoología, El Colegio de la Frontera Sur, Chetumal, Quintana Roo (ECO-CH-H). Oscar Flores-Villela verified all species, except *Ctenosaura alfredschmidti* and *C. defensor*, which were verified by Gunther Köhler. All new distributional records are based on Lee (1996), except the one for *Ctenosaura alfredschmidtii*, which is based on Köhler (2000). Common names follow Liner (1994).

Included herein is one new state record for amphibians and eight for reptiles. Additionally, three amphibians and 24 reptiles represent significant range extensions on the Yucatán Peninsula.

New State Records for Campeche

Anura

Hyla ebraccata (Hourglass Treefrog). 30 km S Xpujil, Ejido Narciso Mendoza, 18°15'35"N, 89°27'07"W (ECO-CH-H 1030); 700 m S Plan de Ayala, 18°03'30"N, 89°17'34"W (ECO-CH-H 1051); and Bella Union de Veracruz, 18°02'00"N, 89°17'23"W (ECO-CH-H 1070). The closest previosly known localities for this species is an isolated population about 200 km northeast in central Quintana Roo and about 100 km to the south in Guatemala.

Lacertilia

Thecadactylus rapicaudus (Turniptail Gecko). 11 km NE AS, 18°11'35"N, 89°44'51"W (ECO-CH-H 0716) and AS (ECO-CH-H 0834). These records close the gap between the known ranges of this species on the northern (Yucatán, Quintana Roo) and southern portions (Guatemala, Belize, and Chiapas) of the Yucatán Peninsula.

Corytophanes hernandezi (Hernandez's Helmeted Basilisk). 11 km NE AS, 18°11'35"N, 89°44'51"W (ECO-CH-H 0612, 0642, 0777) and AS (ECO-CH-H 1440). This species has been previously reported from the base of the Yucatán Peninsula and from isolated records in the state of Quintana Roo. These records extend the range of the species ca. 120 km NW of the closest record in northwestern Belize.

Anolis pentaprion (Lichen Anole). 24 km N Xpujil, 18°43'10"N, 89°23'43"W (ECO-CH-H 0559); AS (ECO-CH-H 0835); and 64 km N Xpujil, 2.5 km E from Highway 269, 19°00'06"N, 89°16'48"W (ECO-CH-H 0964). These records extend the known species range ca. 210 km N of the nearest record in northern Guatemala.

Eumeces sumichrasti (Sumichrast's Skink). AS (ECO-CH-H 1632). This record extends the range of the species ca. 150 km from the nearest record in northwestern Guatemala and closes the gap between the northeastern and southern Yucatán Peninsula populations.

Serpentes

Symphimus mayae (Yucatán White-Lipped Snake). 15 km SE Nueva Vida, Brecha a Ricardo Flores Magon, 18°45'00"N, 89°17'54"W (ECO-CH-H 0591); 10 km N AS, 18°11'35"N, 89°44'51"W (ECO-CH-H 0776). This species was previously known only from the northern section of the Yucatán Peninsula and from an isolated population in northwestern Belize. These records extend the range ca. 150 km NW of the nearest record in Belize and close the gap between northern and southern Peninsula populations.

Tantillita lintoni (Linton's Dwarf Short-tailed Snake). 15 km SE Nueva Vida, Brecha a Ricardo Flores Magon, 18°45'00"N, 89°17'54"W (ECO-CH-H 0820). This record extends the range of the species on the Yucatán Peninsula ca. 200 km N of the closest known locality in northern Guatemala.

Thamnophis marcianus (Checkered Garter Snake). 17 km N Xpujil, 18°39'55"N, 89°24'06"W (ECO-CH-H 0630) and 15 km SE Nueva Vida, Brecha a Ricardo Flores Magon, 18°45'00"N, 89°17'54"W (ECO-CH-H 1334). These records add another apparently isolated population to the known range of the species on the Yucatán Peninsula; the closest known locality being ca. 150 km northeastward in southern Yucatán.

Xenodon rabdocephalus (False Fer-de-Lance). AS (ECO-CH-H 0874) and 30 km S Xpujil, 18°15'35"N, 89°27'07"W (ECO-CH-H 1081). These records extend the range of the species more than 100 km NW of the closest locality in northern Belize.

Range Extensions

Caudata

Bolitoglossa yucatana (Yucatán Mushroom-tongued Salamander). 20 km NE Xpujil, 18°42'33"N, 89°21'50"W (color slide photo voucher [ECO-CH-H A-0001]) and 20 km S Conhuas, 18°22'38"N, 89°53'46"W (ECO-CH-H 1629). These records fill a gap between populations on the northern section of the Yucatán Peninsula and an isolated population ca. 150 km SW of the nearest record in central Campeche. ECO-CH-H A-0001 was found inside a large tank bromeliad (*Achmea bracteata*) located 4 m above ground.

Anura

Hyla loquax (Mahogany Treefrog). Municipality of Hopelchen, 64 km S Dzibalchen, 19°01'51"N, 90°00'53"W (ECO-CH-H 1222) and 23 km SW Xkan-Ha, 19°06'47"N, 89 30'13"W (ECO-CH-H 1234). These records extend the range in Campeche ca. 66 km N of the closest known localities along Mexican Hwy 186.

Gastrophryne elegans (Elegant Narrowmouth Toad). Municipality of Hopelchén: 64 km S Dzibalchén, 19°01'51"N, 90°00'53"W (ECO-CH-H 1216, 1217, 1221, 1224) and 23 km SW Xkan-Ha, 19°06'47"N, 89°30'13"W (ECO-CH-H 1235). These records extend the range ca. 50 km northward from the closest known localities in east-central Campeche.

Testudines

Staurotypus triporcatus (Mexican Giant Musk Turtle). 7 km E Nuevo Becal, El Chorro, 18°35'28"N, 89°15'28"W (ECO-CH-H 1189). This species is known primarily from the southern base of the Yucatán Peninsula. This record expands the known range ca. 106 km E from the closest known locality in central Campeche.

Terrapene carolina yucatana (Yucatán Box Turtle). 8.5 km S Conhuas, 18°27'13"N, 89°53'21W (ECO-CH-H 0792); and AS (CHO-CH-H 1187). This box turtle is known from the northern and western parts of the Yucatán Peninsula. These records represent a range extension of ca. 140 km E from the closest record.

Lacertilia

Ctenosaura alfredschmidti (Schmidt's Spiny-tailed Iguana). AS (ECO-CH-H 0622) and 25 km SSE Conhuas, 18°26'54"N, 89°53'21"W (ECO-CH-H 1293). Previous records for this species were from the type locality at Pablo Garcia village and surroundings (Köhler 1995), ca. 70 km NW of AS.

Ctenosaura defensor (Yucatán Spiny-tailed Iguana). Municipality of Hopelchen, 55 km SW from Dzibalchén, 19°00'51"N, 89°54'35"W (ECO-CH-H 1255). This species is known from northwestern Yucatán as well as from two records in Campeche. This is a range extension for the species ca. 95 km SW and ca. 180 km NE from the two previously known Campeche records.

Iguana iguana (Green Iguana). Municipality of Escárcega, 71 km

SW Escárcega, between El Machetazo and El Naranjo, 18°00'03"N, 90°55'58"W (ECO–CH-H 1642). This is the southeasternmost record for the species in Campeche and extends the range ca. 70 km NE of the closest record in Tabasco.

Sceloporus lundelli (Lundell's Spiny Lizard). AS (ECO-CH-H 0621, 0922, 1146). This species is recognized from the northern and western portions of the Yucatán Peninsula and from an isolated population in central Belize and adjacent northeastern Guatemala. These records represent range extensions of ca. 100 km from the nearest record to the north and close the gap between the northern and isolated southern populations.

Anolis biporcatus (Neotropical Green Anole). 30 km S Xpujil, Ejido Narciso Mendoza, 18°15'35"N, 89°27'07"W (ECO-CH-H 0829). This species has been reported only from the southern end of the Yucatán Peninsula and from an isolated locality in western Campeche. This record extends the range ca. 76 km NW from the closest record in Belize.

Anolis sagrei (Brown Anole). Xpujil, 18°30'30"N, 89°23'51"W (ECO-CH-H 1299). This is the first record of the species from the center of the Yucatán Peninsula and closes the gap between known populations on the eastern and western sections of the Peninsula. Its present distributional pattern is surely the result of human activity, because the species is a human commensal rarely found far from areas of human activity (Lee 1996).

Sphenomorphus cherriei (Brown Forest Skink). 15 km SE Nueva Vida, Brecha a Ricardo Flores Magón, 18°45'00"N, 89°17'54"W (ECO-CH-H 0576, 1324); AS (ECO-CH-H 0843); and10 km NE AS, 18°11'35"N, 89°44'51"W (ECO-CH-H 0880). This species is primarily known from the base of the Yucatán Peninsula and also from an isolated population to the north in Yucatán and adjacent Quintana Roo. These records confirm its presence in the central part of the Peninsula and extend its range ca. 100 km NW from the nearest locality in northern Belize.

Aspidoscelis angusticeps (Yucatan Whiptail). 2 km NW Conhuas, Balam-Ku ruins, 18°33'18"N, 89°56'38"W (ECO-CH-H 1486) and 64 km N Xpujil, 19°00'27"N, 89°17'24"W (ECO-CH-H 0984). This species is known from the northern portion of the Yucatán Peninsula and from two isolated populations in central Belize and adjacent Guatemala. These records extend the range ca. 40 km E and 55 km SE from the nearest known localities in central and northern Campeche, respectively.

Aspidoscelis deppei (Black-bellied Racerunner). 35 km S Xpujil, near Cristobal Colon village, 18°12'44"N, 89°27'04"W (ECO-CH-H 1091, 1096, 1099, 1519, 1520, 1521, 1522). This species has been previously recorded on the Yucatán Peninsula only from extreme southwestern Campeche. These records extend the range southeastward ca. 300 km into the southcentral portion of the state.

Serpentes

Dipsas brevifacies (Snail-eating Thirst Snake). 34 km S Xpujil, Cristobal Colon village, 18°12'44"N, 89°27'04"W (ECO-CH-H 0555, 1083) and AS (ECO-CH-H 0646, 0841, 1160). This species is endemic to the Yucatán Peninsula and known primarily from the northern and eastern portions, although there is one other isolated record close to the city of Belize. These records extend the distribution ca. 50 km SE of the closest locality.

Dryadophis melanolomus (Lizard Eater). 30 km S Xpujil, Ejido Narciso Mendoza, 18°13'49"N, 89°26'20"W (ECO-CH-H 0655) and AS (ECO-CH-H 0767). This species is known to occur on the northern and southeastern sections of the Yucatán Peninsula. These records extend its range ca. 135 km S from the only other records from Campeche.

Imantodes gemmistratus (Central American Tree Snake). 64 km N Xpujil, 2.5 km E from Mexican Highway 269, 19°00'06"N, 89°16'48"W (ECO-CH-H 0960). This species is known to occur in the northern and western parts of the Yucatán Peninsula and from an isolated population in north-central Guatemala. This record extends the range ca. 180 km NE from the closest locality in Campeche and bridges the gap between the northeastern and western Peninsula populations.

Imantodes tenuissimus (Yucatan Blunt-headed Tree Snake). AS (ECOCH-H 0640). This species is endemic to the Yucatán Peninsula and is primarily known from the northern portion, although a record from western Campeche is also documented. This record is the southernmost for the Peninsula and extends the range ca. 200 km S from the closest record in Yucatán.

Lampropeltis triangulum (Milk Snake). 64 km N Xpujil, 2.5 km E from Mexican Highway 269, 19°00'06"N, 89°16'48"W (ECO-CH-H 0959). This record closes the 200 km gap between other populations on the northern and southern portions of the Yucatán Peninsula.

Oxybelis aeneus (Mexican Vine Snake). 24 km N Xpujil, 18°44'10"N, 89°23'40"W (ECO-CH-H 0822); 1 km S Plan de Ayala, 18°03'30"N, 89°17'34"W (ECO-CH-H 1088); and AS (ECO-CH-H 1284, 1439). This species is well documented from the northern, eastern, and southern parts of the Yucatán Peninsula. These records extend the range by ca. 163 km SE from the nearest record in northern Campeche and close the gap within the central section of the Peninsula.

Oxybelis fulgidus (Green Vine Snake). Nuevo Becal, 18°36'29"N, 89°18'01"W (ECO-CH-H 0816) and 1.5 km S Plan de Ayala, 18°03'30"N, 89°17'34"W (ECO-CH-H 1076). This species has been previously recorded from the northern and southeastern portions of the Peninsula. These new records confirm the presence of this species in the central Peninsula, and extend the range ca. 90 km NW from the closest known locality in Belize.

Sibon nebulata (Cloudy Snail Sucker). 30 km S Xpujil, Ejido Narciso Mendoza, 18°15'35"N, 89°27'07"W (ECO-CH-H 0790); 24 km N Xpujil, 18°44'10"N, 89°23'40"W (ECO-CH-H 1007); and AS (ECO-CH-H 1170). These records confirm the presence of this species in central Campeche as proposed by Lee (1996). There is only one previous record for the state, from a locality ca. 230 km W of these records.

Sibon sanniola (Pigmy Snail Sucker). 30 km S Xpujil, Ejido Narciso Mendoza, 18°15'35"N, 89°27'07"W (ECO-CH-H 1098); and AS (ECO-CH-H 1285). This species is endemic to the Yucatán Peninsula and its previously known range included the northern and southeastern sections. These records extend its range ca. 135 km S into the center of the Peninsula.

Urotheca elapoides (False Coral Snake). 10 km NE AS, 18°11'35"N, 89°44'51"W (ECO-CH-0772). This is a well-known

species on the southern end of the Yucatán Peninsula and there is also an isolated population in eastern Yucatán and adjacent Quintana Roo. This record extends the known distribution ca. 130 km SE from the nearest record in western Campeche.

Agkistrodon bilineatus (Cantil). AS (ECO-CH-H 1261) and 2 km NW Conhuas, Balam-Ku ruins, 18°33'18"N, 89°56'38"W (photographic collection, ECO-CH-H R-0037). This species is uncommon, but known from several localities on the northern end of the Yucatán Peninsula and from an isolated population in northern Belize. These records extend the range ca. 170 km SE from the only other state record in northwestern Campeche.

Crotalus durissus (Neotropical Rattlesnake). AS (ECO-CH-H 861, 1147,1441); 24 km N Xpujil, 18°44'10"N, 89°23'40"W (ECO-CH-H 884); 31 km S Xpujil, 18°15'07"N, 89°26'30"W (ECO-CH-H 1549); and 7 km E Nuevo Becal, El Chorro, 18°35'28"N, 89°15'28"W (ECO-CH-H 1419). This species is recorded from most of the Mexican part of the Yucatán Peninsula, except south-central Campeche, and from isolated populations in northern Guatemala and central Belize. These records confirm the presence of the species in southern Campeche, extending the range ca. 60 km S.

Porthidium yucatanicum (Yucatan Hog-nosed Pitviper). Municipality of Hopelchén, Dzibalchén, 19°27'49"N, 89°43'30"N (ECO-CH-H 1204). This species is endemic to the Yucatán Peninsula and previously known only from the northern sections. This is the southernmost record for the Peninsula, the second record for Campeche, and extends the range by more than 80 km S from the closest recognized locality in the northern section of the state.

Acknowledgments.—This work was supported by CONABIO (projects J112 and Q049), the state government of Campeche, and PRONATURA Península de Yucatán A.C. We are indebted to Oscar Flores-Villela for verifying specimens and to Oscar and Sophie Calmé for comments on a previous version of the manuscript. We also thank the staff of the Museo de Zoologia from El Colegio de la Frontera Sur, Unidad Chetumal for assistance during fieldwork, and the staff from Calakmul Archaelogical Site, especially Herminio Chan, who collected some of the specimens reported herein.

The West African herpetofauna is poorly documented, despite having one of the richest snake faunas in Africa (e.g., Böhme 2000; Lawson 1993). Moreover, in many regions snakebite is of exceptional medical significance (see reviews by Spawls and Branch 1995 and Chippaux 1998). This new volume, therefore, fills a much needed gap.

"Chippaux 2001" is a re-edition, revised and updated, of "Chippaux 1999," the chronological successor of Villiers' (1975) famous *Les Serpents de l'Ouest Africain* (also in French and long out of print). The new volume has an agreeable format and a clear and practical organization. It begins with a general section (pp. 11–33) including a presentation of the classification and the evolution of snakes, an introduction to the main morphological characters useful to their identification (with good scale drawings), and a long chapter on venoms, envenomation and its treatment (the author's speciality). The systematics section (pp. 35–249) includes a detailed account for each of the species occurring in the covered area (from Senegal east to the Central African Republic and from Mauritania south to Congo-Brazzaville). It also includes distribution maps, preceded by identification keys to the families, genera, and species. An impressive bibliographical section of 33 pages terminates the book. The text is accompanied by eight color plates, showing in total 55 photographs (illustrating four clinical envenomation cases and 47 snake species).

Several book reviews of the first edition have appeared, mentioning some important corrections. We concur with Hughes (2000) and Akani (2002) that the "*Dasypeltis fasciata*" shown in photograph 18 is in fact *D. scabra*, and that the "*Thelotornis kirtlandii*" (photograph 30) is *T. capensis*. Hughes (2000) also suggested that the "*Psammophis phillipsii*" in photograph 36 (from near Cotonou airport, Bénin; pers. comm. J.-P. Chippaux) is *P. sibilans*, that "*P. rukwae*" (photograph 38) is probably *P. sudanensis*, and that the viper "*Echis leucogaster*" (photograph 52) is *E. ocellatus*. The numbering of the pictures and their specific identification (except for the *Echis*, which has been corrected) remain unchanged in the second edition. We add that "*Grayia tholloni*" (photograph 15) is a (starving ?) *G. smithii* (the specimen probably originating from Togo; J.-P. Chippaux, pers. comm.). It would have been preferrable for each photograph to be accompanied by the locality of the specimen. It should be noted also that "*Grayia smythii*" should be spelled *G. smithii* (see Pauwels et al. 2000), and "*Elapsoidea güentheri*" should have a double i and lack an umlaut. Other misspelled scientific names include "*Bothrophtalmus*" (p. 54, map; = *Bothrophthalmus*) and "*Lycophidion multimaculata*" (p. 76, right column; = *multimaculatum* as the gender of *Lycophidion* is neutral).

It is a great pity that scolecophidians, although represented by some 30 species in the area covered by the present opus (i.e., 15 % of the 195 local species recognized by Chippaux) are treated in only two pages, without any key to the genera or species. However, a volume wholly dedicated to the African Typhlopidae (Roux-Estève 1974) is available and, moreover, the Leptotyphlopidae and Typhlopidae of Africa have been dealt with in identification keys by Meirte (1992).

An excellent feature of Chippaux's book is that head scalation drawings have been provided for many species, which is very useful for identification. In general, at least one species per genus has so been illustrated, but unfortunately not for the genera *Rhinoleptus* (Leptotyphlopidae), *Ramphotyphlops*, *Rhinotyphlops* (Typhlopidae), *Hemirhagerrhis* (Colubridae), *Poecilopholis*, *Xenocalamus* (Atractaspididae), and *Cerastes* (Viperidae). A few drawings should be corrected, including the lateral view of the head of *Malpolon moilensis* which shows one preocular, whereas the species account (p. 158) notes "la préoculaire inférieure est au moins trois fois plus petite que la supérieure" ["the lower preocular is at least three times smaller than the upper one"]. The scalation drawing for *Dromophis lineatus* (p. 162) shows two preoculars, while the species and genus accounts specify only one. The lateral view of the head of *Atractaspis reticulata* (p. 187) shows fused internasals and prefrontals (perhaps a particularity of the illustrated specimen, but at least a very atypical configuration for the species); the upper view of the head of *Polemon gracilis* (p. 204) indicates a broad supralabial/prefrontal contact although the lateral view shows an absence of contact (same remark as above). For this latter species, Chippaux wrote (and this is also visible in his drawing) "aucune labiale supérieure n'est en contact avec la pariétale" ["none of the supralabials contacts the parietal"], *contra* de Witte and Laurent (1947). Those uncertainties concerning the drawings could be removed if the illustrated specimens could be traced and examined, i.e. if the drawings had been accompanied by the museum collection numbers of the specimens on which they were based (the same comment also applies to the hemipenis and maxillary drawings).

The generic allocation of some species remains debatable, e.g., *Charina* for *Calabaria* (sensu Kluge 1993) has not received common acceptance; African *Geodipsas* have been transferred to the new genus *Buhoma* (Ziegler et al. 1997); and the use of *Haemorrhois* for all African *Coluber* is premature—although *algirus* has been transferred to *Haemorrhois*, *Coluber dorri* remains anomalous among African racers and should remain in *Coluber* sensu lato (Schätti and Utiger 2001). It should be noted as well that the Dispholidini has recently been revised (Broadley and Wallach 2002) with resurrection of *Rhamnophis* for *aethiopissa* and *batesi*. Molecular studies have also shown that the two races of Gaboon adder show sufficient divergence to be treated as separate species (Lenk et al. 1999). Both species therefore occur in the region, and *Bitis rhinoceros* is endemic to the Upper Guinea forest.

Inclusion of the summarized classification of African colubrids (p. 50) by Bogert (1940), while of historical value, does not reflect current understanding of relationships among African snakes and could be easily deleted. Similarly the groupings of atractaspids by features of dentition and hemipenes (p. 177) is of little value and is, moreover, inaccurate as *Aparallactus modestus* lacks back fangs.

The identification keys and generic and specific accounts are very useful, but some mistakes are present. The general key to the Colubridae (pp. 51–53) presents two couplets numbered 31 but no couplet 33, which makes the use of the key between couplets 31 and 45 questionable. The second part of couplet 37: "de 15 à 21 rangées dorsales" ["15 to 21 dorsal scale rows"], is erroneous, because it refers to various genera, of which *Philothamnus* includes species with only 13 dorsal rows. On pages 70–71, it is stated that *Lycophidion*, whose "frontale est plus large ou aussi large que longue" ["frontal is wider than or as wide as long"], can be distinguished from *Chamaelycus* because the latter possesses "une frontale plus large que longue" ["a frontal wider than long"]. There is also a contradiction within the account of *Lycophidion nigromaculatum* (p. 74) regarding the number of preoculars (1 vs. 2). Chippaux (p. 94) indicated that *Hydraethiops laevis* shows a single internasal, while it is in fact either single or divided (Pauwels et al. 2002) as indicated in the original description. The key for the genus *Thrasops* (p. 103) begins with a first couplet leading to a single vs. divided anal plate, but the introduction to the genus incorrectly characterizes all species as having a divided anal. In the presentation of the genus *Hapsidophrys*, Chippaux (p. 119) wrote that both species show a single preocular, while two are visible on the lateral head scale drawing of *H. lineatus*, in agreement with the species account which states "1 préoculaire, parfois 2" ["1 preocular, sometimes 2"]. Chippaux indicates a maximal number of 143 subcaudals for *Dispholidus typus*, which corresponds to that shown by the only known Gabonese specimen, plotted on the map on p. 153. This specimen, however, is probably a *Thrasops* (Hughes 1983). In the introduction to the Elapidae (p. 207), the author states that the loreal scale is always absent in the group, but on p. 220, in the presentation of the cobras of the genus *Pseudohaje*, one finds "loréale généralement absente" ["loreal generally absent"] (as previously noted by Hughes 2000). The generic account for *Paranaja* (p. 227) indicates that the dorsal scale rows are oblique, contrary to the species account where they are said to be straight.

Although the nomenclature of scales has been very well explained and illustrated in the general section, these definitions are not always taken into account in the species accounts. For instance, the drawing of *Scaphiophis albopunctatus* (p. 116) shows two preoculars, no subocular and two postoculars, but the species account states that there is one preocular, two or three suboculars and two or three postoculars. For *Thrasops batesii* too (p. 107), what should be called a subocular following the earlier definitions on p. 16, is called a postocular.

The maps, each dotted and tinted, most often dealing with a single taxon, give a good idea of the general distribution of the species. Point localities are based on literature records (white dots) and personal observations of the author (black dots). It is important to draw the attention of non French-speaking readers to the fact that the map tinting is based on the probability of the presence of the species "en fonction de critères écologiques (climat, végétation, degré d'anthropisation)" ["according to ecological criteria (climate, vegetation, degree of anthropisation)"]. As Hughes (2000) and Akani (2002) have noted, the point localities for most species are drawn mainly from the French literature, and many localities from English language publications have been omitted (even if the articles are listed in the bibliography). In addition to this deficiency we also noted important discrepancies between the text and the distribution maps, notably for *Dipsadoboa underwoodi*, *Gonionotophis grantii*, *Lamprophis virgatus*, *Lycophidion irroratum*, *L. multimaculatum*, *Psammophis phillipsii*, *Telescopus variegatus*, *Atractaspis dahomeyensis*, *Polemon gabonensis*, *P. gracilis*, and *Causus resimus*. The distribution of *Python sebae* (p. 47) is still given as extending to South Africa, although southern and eastern populations have since 1984 been referred to *P. natalensis* (Broadley 1984). Chippaux (p. 238) included in the map for *Atheris broadleyi* dots intended to depict the distribution of *A. squamigera* in the map provided in the original description of the former species, and thus erroneously shows *A. broadleyi* from Gabon and Congo-Brazzaville. *Echis jogeri* Cherlin, 1990 (ignored in Chippaux 1999) is dotted on a map but not discussed in a detailed species account. This was attributed to the "nombre de spécimens trop faible (4 exemplaires au total) pour permettre une plus ample description" ["too low number of specimens (4 in total) to allow for a more complete description"], even if this species is considered as "probablement valide" (p. 244). However, other species known from less than four specimens, including some taxa that are probably invalid, such as *Mehelya riggenbachi* and *Atractaspis coalescens* (each known from a single specimen), are discussed in dedicated accounts. The genus *Eryx*, included in the first edition on the basis of the presence of *E. somalicus* in the Central African Republic, has disappeared without comment from the second edition. The map for *Mehelya capensis* shows a strong overlap of the distribution of the subspecies *capensis* and *savorgnani*, indicating they should be better treated as distinct species, and similar comments could be made for the sympatric subspecies *lineatus* and *brunneus* of *Bothrophthalmus lineatus*. Type localities are indicated in French, but should be given in the language of the original description in order to avoid possible misinterpretations due to translation.

Despite these relatively few errors and problems this book is a remarkable reference work and will serve as a useful starting point for herpetologists in the field and in the laboratory. It is an excellent synthesis that all naturalists interested in the rich African fauna will want to consult. We strongly recommend its acquisition by all natural science libraries.

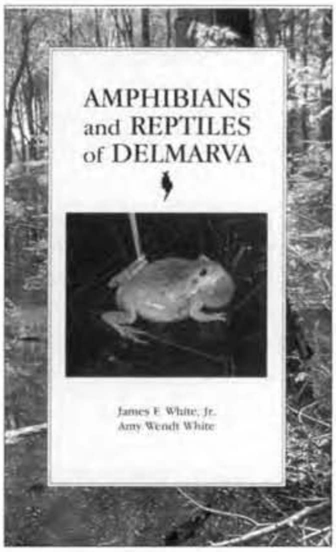
e-mail: dpike1@towson.edu



Local and regional field guides are important outlets of public education, working to dispel the myths surrounding reptiles and amphibians by presenting valid information in a readable manner. Because of the directed focus of these efforts, these guides also work to include extensive detail of both habitats and species that occur in these generally small areas. *Amphibians and Reptiles of Delmarva* is no exception, combining detailed species accounts with simple habitat descriptions that will assist nature enthusiasts and experienced herpetologists alike in identifying species and learning about the natural history of this diverse coastal herpetofauna. This book focuses on the herps of the Delmarva Peninsula, which sits on the mid-Atlantic Coast, encompassing all of Delaware and extending south into part of Maryland and Virginia east of the Chesapeake Bay. The Delmarva represents an interesting zoological and botanical transition zone because many species reach either the northernmost or southernmost range of their distributions in this area.

Amphibians and Reptiles of Delmarva is a pocket-sized (18.8 cm x 11.5 cm) book ideal for field identification of specimens. It begins with an introductory explanation of the nomenclature adopted, how to use the field guide, and a brief history of herpetology in the Delmarva region. Although the history section presents only a short summary of the herpetologists who have worked in this region, it is filled with references from the primary literature, most of which are difficult to locate. Next is an explanation of the physiography of the region, which provides an excellent overview of some of the geographical features that make up the Delmarva. Additionally, it provides a short summary of the habitat types in the area, as well as a list of the most common groups of reptiles and amphibians found in each habitat. The third section is aimed towards the casual nature observer or amateur naturalist, and provides detailed information on observing, identifying, and handling amphibians and reptiles. Also presented are the names and addresses of individuals and organizations interested in range extensions, sightings of rare species, or simply in assisting with identifications of observed animals.

The real treasure of this book lies in the species accounts, describing in detail the 73 species recorded from or suspected as occurring on the Delmarva. A brief overview of each species is presented, including a description, a list of morphologically similar species, overall range, range and status (very common to extremely rare) on the Delmarva, habitats where the species can be found, and life history. Distribution maps are also presented, with the entire county shaded to denote species presence. Nestled in the center of the species accounts are color photographs of each species presented in the text as well as some of the previously described habitat types. The photographs are arranged by taxonomic group, allowing easy preliminary identification of observed species using only the photographs, which is helpful for those unfamiliar with identifying species from written descriptions. The final section overviews conservation issues as they relate to the Delmarva, including a table of rare species with their State, Federal, and National Heritage rankings, as well as a description of the significance of each category. Presenting even a brief overview of conservation issues in a field guide aimed at a broad audience is an excellent way of educating herpetology enthusiasts about the effects of humans on the species they are interested in. Finally, an appendix presents a species list with room to write in short field notes for each species.

Although the authors follow the nomenclature of Crother (2000) for both common and scientific names, several of the common names used differ from those used in other regional field guides (e.g., little brown skink for ground skink, *Scincella lateralis*, northern diamond-backed terrapin for northern diamondback terrapin, *Malaclemys terrapin terrapin*), possibly causing some confusion for those unfamiliar with scientific nomenclature. However, the designation of consistent common names must begin somewhere and I applaud the authors for using a previously published nomenclature throughout their work. The distribution maps are quite small (3.4 cm x 1.2 cm) and lack detailed species ranges, as one species record is presented as equivalent to a true county-wide distribution. I feel more detailed distribution maps are useful to those searching for specific species, with each museum specimen locality designated (e.g., Palmer and Braswell 1995) or at least more precise ranges presented (e.g., Bartlett and Bartlett 1998) so that the reader can get a true idea of the distribution of a species with regard to habitat and geographical features, rather than political boundaries. Additionally, a smaller-scale map depicting the entire states of Delaware, Maryland, and Virginia, including the Delmarva's location within this area at the beginning of the book would help those unfamiliar with the region to visualize the relationship between the peninsula and the mainland.

This book is exceptionally thorough and well organized for being focused on such a small geographic region and I recommend this book to anyone interested in coastal herpetofaunas, especially those interested in biogeography. The cost is a bargain considering the wealth of information presented and the beautiful color photographs. It makes an excellent field companion and will serve as a general guide to those unfamiliar with the herpetofauna of the mid-Atlantic region, both on and near the Delmarva.

JOSÉ P. ROSADO
Department of Herpetology, Museum of Comparative Zoology
Harvard University, Cambridge, Massachusetts 02138, USA
e-mail: jrosado@oeb.harvard.edu

This book is a revision of John Simmons' 1987 SSAR Herp Circular Number 16, which is now out of print. Since the publication of the first edition of this volume, much has changed in terms of both collecting herpetological material and managing these collections. An indication of this change is the length of the circular. The new edition has increased from 56 pages of text to 108, references have increased from 14 pages to 25 pages, and three appendices have been added to provide additional sources of information.

The publication is divided into four parts covering the following topics: I. A Brief History of Systematic Collections, II. Field Collecting, III. Preservation of Specimens, and IV. Museum Collections. To the extent that the stated goal of the author is to provide "an even better, but equally flexible framework for collection care in line with recognized professional standards and practices," I have to say that he has gone beyond his own expectations.

Part I is an addition to the first edition. It presents a historic overview of collecting as a human endeavor, the development of museum collections, and the evolution of preservation technology and record keeping. Collecting has long been a part of our natural learning process. The documentation of natural diversity and the collection of curiosities have long histories. Preservation techniques predate the development of collections and museums, but the advent of new and more effective preservation methods facilitated the rise of modern natural history museums and transformed systematic collections from 'cabinets of curiosity' for the select few, to a worldwide resource documenting natural diversity. Following Whitehead's (1970) historical periods, Simmons discusses the changing nature of systematic collections as an interaction of our search for knowledge and the development of the technologies to preserve and conserve natural history specimens through time. In his section on the future of systematic collections, the author points to the growing value of systematic collections as new ways of obtaining data from specimens (e.g., DNA extraction from preserved specimens) are discovered and new uses for collections (e.g., biodiversity informatics) are developed. As fieldwork and collecting become more difficult and expensive, the value of present holdings will only increase.

The bulk of the book is devoted to the topics of collecting and preservation, and to a discussion of the framework for a properly managed systematic collection. From the onset, it is clear that these go hand in hand. Given the expense, time, and effort that go into the preparation for and execution of any given field trip, there is a corresponding need for the proper care and curation of the collections realized. If not, all would be wasted.

In Part II, the many field collecting strategies, methodologies, and techniques that the herpetological community has developed are reviewed, providing both an introduction to beginners as well as a benchmark for experienced workers. In this section John also thoroughly covers preparing for a collecting trip, providing a discussion of what needs to be considered and accomplished before departure. Much of the material covered might seem obvious, but I have found checklists much more reliable than my memory. Appendix II serves as a guide to how to prepare and what to pack and can be adjusted to fit the type and duration of any field trip. One of the more important elements of preparation involves obtaining the appropriate permits. It is imperative that any collecting is done legally, with all the proper permits and documentation constituting an integral part of the collection itself. Without these, the legal ramifications can be extensive and severe, affecting not only the individual collector, but also the institution that accessions the collection. One must also be prepared to anticipate problems; it is not unheard of to have all the appropriate documentation and still run into difficulties.

Part III of the book addresses the actual preparation and fixing of specimens and proceeds step by step from the field to the collection shelf. This section has tripled in size from the previous edition and its completeness attests to the importance of proper preparation and documentation procedures to maximizing the value of each specimen collected. The author has provided an excellent resource for collectors, curators, and collection managers. He supplements the discussion with alternatives and associated references. This is where Simmons' experience really shows. For example, he discusses preferred methods for preservation of specimens, laying out alternatives depending on the ultimate use of the specimen. His discussion on fixation and preservation clearly explains the actual fixation process and reviews specific methods for preserving amphibians and reptiles, pointing out things easily forgotten, for example, tying off an everted hemipenis so that it remains fully extended.

The author's coverage of techniques is extensive and more than I can mention in this review. Although I may disagree with a procedure here or there or maybe just do things differently, I found the discussion complete and helpful, with ample references to sources providing detailed information about the recommendations and techniques mentioned. Inherent in the discussion is the need to continue to develop these techniques and to document

current procedures to assist future workers to understand better what has happened to specimens. Such documentation, at a procedural level, gives another layer of added value to specimens.

In Part IV, Museum Collections, dealing with collection management, Simmons puts everything together. It accounts for almost half of the text as a whole. What should happen to the specimen and its associated data once collected, processed, and placed on the shelf? Simmons defines the most important functions of collection management as (1) maintaining the integrity of specimens and their associated data; (2) maintaining specimens and data in optimum usable condition; and (3) making specimens and data available for appropriate use. His discussion outlines professional standards and procedures and defines what museum collections should strive for operationally. He considers the physical conservation of specimens and related data, as well as factors that affect the longevity and usefulness of specimens. Preservation techniques, storage conditions, environmental parameters, and laboratory facilities are thoroughly reviewed as are personnel and their respective roles and responsibilities and both the physical and administrative management of the collection. All in all, it is a concise discussion of how to manage a collection and a museum, providing specific recommendations based, in part, on personal experience.

This publication is an excellent summation of the progress that has been made in the field of conservation of herpetological collections and is a tribute to the author's continued efforts to expand our knowledge. Simmons provides the reader with a detailed guide to herpetological collecting and the management of museum collections. This is a publication that should be on the desks of all museum professionals, worn from use. The museum community owes John a debt of gratitude for providing such a tool to assist us in the execution of our trust. I only hope that enough copies have been printed for all who should read it.

PUBLICATIONS RECEIVED

The Herpetofauna of Shek Kwu Chau, South China Sea, with Descriptions of Two New Colubrid Snakes, by James Lazell. 2002. Memoirs of the Hong Kong Natural History Society 25. 82 pp.

This memoir documents the herpetofauna of Shek Kwu Chau, a small island in the South China Sea near Hong Kong. Following an introduction to the geological and historical background of the island, accounts are provided for 24 species of amphibians and reptiles, including the new taxa *Ahaetulla prasina medioxima* and *Dendrelaphis hollonrakei*. Most accounts provide detailed systematic and/or natural history notes and some contribute significantly to the knowledge of poorly known forms. The work concludes with general considerations of life histories and biogeography. It is illustrated by numerous graphs, maps, line drawings and photographs. This contribution should be of special interest to herpetologists studying the tropical Asian fauna, island biologists, snake systematists, and ecologists.

Anakondas, by Lutz Dirksen. 2002. Natur und Tier-Verlag GmbH, An der Kleimannbrücke 39/41, D-48157 Münster, Germany (www.ms-verlag.de). 190 pp. Hardcover. 48.00 €(approx. US $52.00). ISBN 3-931587-43-6.

This book, written in German, is a monographic revision of the genus *Eunectes*, based on the doctoral dissertation of the author. It begins with short overviews of the systematic relationships of anacondas, current taxonomy (including synonymies), paleontology, and conservation status, as well as a brief summary of South American geography, geology, climatology, vegetation, and fauna. More than 750 specimens were examined in the course of the work and morphological and color data were subjected to multivariate analysis, while RAPD data were used to generate a phylogeny for the genus. Four living species of anacondas, including a new species, *E. beniensis*, are recognized. For each taxon a diagnosis is provided and color, pattern, morphometry, scalation, skeletal and dental anatomy, sexual dimorphism, hemipenial structure, reproduction, feeding, behavior, captive care, and commercial trade are discussed. The text is complemented by many color photographs, tables, and graphs dealing with all aspects of anacondas, their anatomy, biology, and habitats. Point locality maps and country-by-country discussions of distribution clarify the ranges of each taxon and reveal previously unrecognized patterns. The book concludes with summaries in German, English, French, and Spanish and a bibliography with approximately 250 entries. "Anakondas" summarizes a wealth of information about these giant snakes and will be a valuable addition to the libraries of snake systematists, morphologists, and those interested in the fauna of South America.

Die Äskulapnatter – *Elaphe longissima*, Verbreitung und Lebensweise in Mitteleuropa, by Axel Gomille. 2002. Edition Chimaira, Friedberger Anlage 14, D-60316, Germany (frogbook@aol.com). 158 pp. Hardcover. 27.80 €(approx. US $30.00). ISBN 3-930612-29-1.

This book presents a detailed picture of the distribution and natural history of the Aesculapian snake, *Elaphe longissima*, the largest snake (to 1.8 m or more) of central Europe. The author dispels earlier views that the species, which has been important in mythology and symbolism since ancient times, was translocated by the Romans. Rather, its patchy distribution in several river valleys in central Europe is relictual and reflects the species' need for warm, humid forest conditions. A large section of the book is devoted to a study of the snake in the Neckar-Odenwald region of Germany, one of the isolated northern localities where the snake occurs. Ecological and population data are presented and fine scale correlates of local distribution are discussed. The book also hypothesizes historical processes and ecological constraints that have contributed to current reptile distributions in central Europe and reviews aspects relevant to the conservation of the aesculapian snake in Germany and elsewhere. The volume is illustrated by

five maps, nine graphs, and more than 80 photos and illustrations, mostly in color. All figure and table legends are provided in both German and English and there is a five-page English summary. A bibliography of almost 200 references rounds out the book. In addition to those studying the European herpetofauna, "Die Äskulapnatter" should be of special value to anyone interested in questions of herpetofaunal distribution and their relationships to Pleistocene and Holocene events.

Lizards, A Natural History of Some Uncommon Creatures – Extraordinary Chameleons, Iguanas, Geckos, & More, by David Badger, photography by John Netherton. 2002. Voyageur Press, P.O. Box 338, Stillwater, Minnesota 55082, USA (books@voyageurpress.com). 160 pp. Hardcover. US $29.95 + $4.95 shipping and handling. ISBN 0-89658-520-4.

This is the latest popular book from the same author/publisher combination that has produced the recent titles "Frogs" and "Snakes." The book is aimed at a general audience and endeavors to introduce the basic biology and diversity of lizards through a combination of clear, simple narrative and excellent photography. Most of the information is drawn from secondary works in herpetology, but is accurate and engagingly written. The book is divided into four chapters, shorter treatments of "Lizards and Humans" and "Lizard Conservation" and longer ones on "Physical Characteristics and Behavior" and "Families and Species." The first of these sections points out the role of lizards in human societies around the world and their significance to modern popular culture. Twenty-nine species are featured with two page entries including a color photograph and a general text, highlighting interesting aspects of the species' biology. Many additional species are illustrated in the "Physical Characteristics and Behavior" chapter under such headings as "limbs and locomotion," teeth and venom," "thermoregulation," and "predation." Scientific names are provided in the species profiles, but not in the rest of the book. In addition to a bibliography of more than 120 references, the book is fully indexed. This volume would be appropriate for younger readers or other novice herpetologists. Very good to excellent photography and clear explanations should help engender a real appreciation for lizards.

A Field Guide to Amphibian Larvae and Eggs of Minnesota, Wisconsin, and Iowa, by Jeffrey R. Parmelee, Melinda G. Knutson, and James E. Lyon. 2002. U.S. Geological Survey Information and Technology Report USGS/BRD/ITR-2002-0004 (available from National Technical Information Service, 5285 Port Royal Road, Springfield, Virginia 22161, USA). 38 pp. Softcover.

This slim volume provides species accounts for the eight salamanders and 21 frogs occurring in the three upper Midwest states covered. Each account includes a black and white illustration of the larval form (a female guarding eggs is shown for the direct developing *Plethodon cinereus*), a shaded distribution map with county boundaries shown, and a short text section describing the eggs and larvae as well as comments about distribution and/or adult habitat. Some similar species are combined into single accounts. Circular field keys to eggs, salamander larvae, and tadpoles are a highlight of the guide and are supplemented by simple line drawings that illustrate terms used in the keys. The book also provides short sections on preserving eggs and larvae and raising larvae, and concludes with a short bibliography. It should prove especially valuable to those involved in amphibian monitoring. Because many of the species dealt with are broadly distributed in the Midwest and the eastern United States, the guide will have utility outside of the three states noted in its title.

Exploring Animal Behavior in Laboratory and Field, edited by Bonnie J. Ploger and Ken Yasukawa. 2002. Academic Press, 525 B Street, Suite 1900, San Diego, California 92101-4495, USA. 472 pp. Softcover. US $44.95. ISBN 0-12-558330-3.

This lab/field manual is subtitled "An Hypothesis-Testing Approach to the Development, Causation, Function, and Evolution of Animal Behavior" and is divided into major sections dealing with "Describing Behavior," "Causation," "Development," and "Adaptation and Evolution." The 35 chapters by 50 contributors use a diversity of animals to illustrate principles in the context of experimentation and hypothesis testing. The book is written for the student in an introductory animal behavior class and each chapter includes an introduction to the topic and subject organism(s), materials, experimental procedure, hypotheses and predictions, data recording and analysis (with sample data sheets in some cases), questions for discussion and a literature cited section. Important terms are highlighted in bold and are defined in an extensive glossary at the end of the book. Herpetological exercises are: Chemoreception in Lizards (C.O. Krekorian), Behavioral Thermoregulation in Field Populations of Amphibian Larvae (H.H. Whiteman and N.L. Buschhaus), Aggregation and Kin Recognition in African Clawed Frogs (K.L. Anderson and B.J. Ploger), and Vocal Behavior and Mating Tactics of the Spring Peeper (*Pseudacris crucifer*): A Field Exercise in Animal Behavior (D.C. Forester). Other experiments use birds, insects, fish, and mammals, including humans. Appendices dealing with the treatment of animal subjects, the ethics of human subject use, and an introduction to statistics round out the volume. Instructors of laboratory courses in animal behavior should consider this text for adoption.

The Lizards of Italy and Adjacent Areas, by Claudia Corti and Pietro Lo Cascio. 2002. Edition Chimaira, Friedberger Anlage 14, D-60316 Frankfurt am Main, Germany. 165 pp. Hardcover. US $39.95. ISBN 3-930612-68-2.

This book treats the 27 species of lizards (in five families) occurring in Italy and the neighboring areas of Corsica, Istria, and Malta. It commences with an overview of the region and a discussion of zoogeography, highlighting the relatively high level of endemism among the region's lizards. Each species account provides Latin, English, and Italian names and a relatively detailed description, including information on sexual dimorphism. This is followed by sections on "Distribution, zoogeography and taxonomy" and "Biology and ecology." These sections are typically several pages long and cite original sources extensively. Each ac-

count is illustrated by a shaded distribution map and by several color photos, each captioned with the corresponding locality. Representative habitat photos supplement the text. The volume concludes with a short section on conservation and an extensive bibliography of more than 500 references, although there is no index. The book is the first major treatment of the Italian saurofauna in English, and should appeal to herpetologists interested in the lizards of Europe, and particularly to those interested in lacertids, as these are represented by seven genera and make up more than half of the species covered.

Herpetology in Montana, by Bryce A. Maxell, J. Kirwin Werner, Paul Hendricks, and Dennis L. Flath. 2003. Society for Northwestern Vertebrate Biology, Olympia, Washington (www.snwvb.org). Northwest Fauna Number 5. Peabody. viii + 138 pp. Softcover. US $12.00 + $1.50 postage and handling ($2.50 foreign). ISBN 0-912532-57-2.

This is not a field guide, and there are no photographs of amphibians or reptiles, but this book provides a wealth of information about the 12 amphibians and 17 reptiles of America's fourth largest state. It begins with a thorough review of the history of herpetology in Montana and then reviews the status of information on the fauna based on published papers, voucher specimens (more than 4600), and well documented observations (more than 7000); checklists and keys (to amphibian eggs and larvae, as well as adults of both classes) follow. The bulk of the book is occupied by species accounts. These include the sections: Comments (general comments on species status in Montana), Earliest Literature Record, Earliest Voucher Record, Maximum Elevation Record, Maximum Elevation Voucher Record, Voucher Record Summary (listing all museum specimens by county), and Bibliographic Index (with references sorted by topic). The distribution of each species is plotted on a large point locality map of the state that shows county boundaries as well as rivers and montane regions; voucher and sight records are distinguished by different symbols. Short accounts are provided for seven species or subspecies of possible occurrence and for 12 exotics reported from the state. *Herpetology in Montana* concludes with a bibliography of more than 600 references and brief sections on reporting observations of amphibians and reptiles and preventing the spread of viral and fungal pathogens. Herpetologists with interests in the fauna of the Pacific Northwest, the Rocky Mountains, Great Basin, or Great Plains, as well as those interested in the history of American herpetology, will find this book a welcome addition to their shelves.

Frogs of the Great Lakes Region, by Jim McGrath. 2002. Nature Discovery, 5900 N. Williamston Road, Williamston, Michigan 48895, USA. Compact Disc. US $14.00 + $2.00 postage and handling.

This CD features the calls of 13 species of anurans of the Great Lakes region, presented in chronological order of emergence and breeding. The calls are presented with narrated commentary in an instructional format geared towards those participating in amphibian surveys. An additional 13 tracks, with titles such as "Marsh

Mellow Peepers" and "April Showers Bring May Fowler's" provide more than 45 minutes of uncommented chorusing. A small booklet accompanying the CD features 12 color photos of frogs (*Hyla versicolor* and *H. chrysoscelis* are treated together), and briefly lists identifying physical characteristics and describes the breeding period, breeding call, and breeding habitat. As most of the species have broad distributions in eastern North America, the CD may be of interest to frog enthusiasts across the Midwest and adjacent areas.

Erratum

Two geographic distribution notes authored by M. J. McCoid (2002, 33:321, 322) require corrections for species identifications. In the first instance, the specimen reported as *Ctenosaura pectinata* (TCWC 84723) is actually *C. similis*. In the second case, the specimen reported as *Hemidactylus turcicus* (TCWC 84910) is actually *H. garnottii*. Identifications of both were confirmed by James R. Dixon and R. Kathryn Vaughan.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.html>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor or Managing Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR Treasurer (Dr. Theodora Pinou; contact information on inside front cover) or from the SSAR web page (http://www.ssarherps.org/pdf/Adrates.pdf).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Donald Schmitt, SSAR Membership Office, P.O. Box 253, Marceline, Missouri 64658, USA. All rights reserved. No part of this periodical may be reproduced without written permission of the Editor. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below), regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35

Herpetological Review

Volume 34, Number 3
September 2003

fore, the incidence of breakage could be expected to differ at each locality, and to change over time.

In the data set that included recaptures, snakes probably averaged older and therefore had a higher ratio of broken tails, but the trends for the two data sets are similar. In both samples, females had higher frequencies of broken tails than males, and adults had higher frequencies of broken tails than juveniles (Tables 1–4). Tail breaks are not common in first-year snakes, and it seems that immatures seldom rely on autotomy for defense. Of first-year young (less than 350 mm SVL) only 2.42% of 452 had broken tails, but for 886 larger snakes the ratio was 13.7%. As adult size is attained the incidence of tail breaks rises sharply, especially in females. The incidence of breakage was 10.3% in 399 males and 16.7% in 487 females. It is not known how much tail loss affects survivorship.

Acknowledgments.—I thank my daughter, Alice F. Echelle, and Galen L. Pittman for advice concerning statistics.

Using Rims to Hinder Amphibian Escape from Pitfall Traps

MARC J. MAZEROLLE
Centre de Recherche en Biologie Forestière, Pavillon Abitibi-Price
Université Laval, Québec, Québec G1K 7P4 Canada
e-mail: marc-j.mazerolle.1@agora.ulaval.ca

Pitfall traps, either arranged in grids or associated with drift fences, are commonly used to assess amphibian species richness and abundance in various habitats (Corn 1994). However, trap efficiency is believed to differ across species, as some species are more likely to be captured and remain in traps than others (e.g., tree frogs can climb out, large individuals may jump out; Corn 1994). This is particularly important in large-scale studies with distant sites or large numbers of traps that cannot be checked daily (e.g., Bury and Corn 1987; Degraaf and Rudis 1990; deMaynadier and Hunter 1998; Mazerolle 2001; McLeod and Gates 1998; Stockwell and Hunter 1989). To overcome this problem, researchers have made different modifications to traps, such as varying trap size (Vogt and Hine 1982), or adding funnels (Corn 1994; Vogt and Hine 1982), side flaps (Nadorozny and Barr 1997), pivoting top flaps (Christiansen and Vandewalle 2000), or rims (Bury and Corn 1987; Stenhouse 1985). However, very few investigators have experimentally tested the effectiveness of their alterations against amphibian escape (but see Brown 1997; Christiansen and Vandewalle 2000; and Vogt and Hine 1982). In this paper, I present data collected in field conditions to test the effectiveness of pitfalls with and without rims in hindering amphibian escape (i.e., animals being missing from the trap).

All experimental trials were conducted in Rankin Bog (46°48'N, 65°00'W), a peat bog within Kouchibouguac National Park, in southeastern New Brunswick, Canada, during the summers of 1998, 1999, and 2001. Pitfall traps consisted of 11.4-L plastic buckets (24 cm diameter x 30 cm height), each of which was placed in a shallow hole ca. 10 cm in depth. This ensured that the tops of the buckets were well above the bog surface to alleviate the probability of an accidental capture during trials. Each trap was a quarter-filled with water, and a thick mat of *Sphagnum* moss was added in the buckets to provide cover (Mazerolle 2001). Rims were fashioned from bucket lids by cutting out their center portion, leaving a margin of 2 cm. These rims were added to some traps to test whether the presence of rims helps prevent escapes from the pitfall traps.

A predator exclosure was built around the entire array of buckets in 2001 to test whether escape rates were confounded with avian or mammal predation at the site during 1998 and 1999. The exclosure (0.91 m in height and 7.2 m in circumference) consisted of plastic snow fencing with a mesh size of 1 cm^2. The top of the exclosure was covered with nylon window screening fastened with clothespins to hinder avian predation.

I collected individuals of five amphibian species (see Table 1) from breeding ponds in the proximity of Kouchibouguac National Park. Amphibians also were collected during night driving surveys conducted on rainy evenings (Shaffer and Juterbock 1994) between April and September of 1998, 1999, and 2001 in the same area. Individuals were temporarily housed in a cool dark room and used in experimental trials within 36 h of capture. At the beginning of experiments, I measured the snout–vent length (SVL) of each amphibian. Individuals were randomly allocated to buckets fitted with or without rims, with the restriction of a single individual to each bucket. During a given trial period, the number of traps employed varied depending on the number of amphibians at hand (range 5–27 traps); for each species, half the individuals were randomly allocated to traps with rims, with the other half assigned to traps without rims. In those cases with an odd number of amphibians, the last individual was randomly allocated to one of the two trap types. The traps were arranged in a small grid of ca. 5 m^2. Traps were checked four days following the introduction of amphibians to assess whether animals were present or absent. Each individual was used only once, and was released at its original capture location if it was present in the trap at the end of the trial. A total of 256 individuals was tested over 17 four-day periods during 1998, 1999, and 2001.

I used logistic regression (Hosmer and Lemeshow 1989) to assess, for each species placed in pitfall traps, the effect of trap type (i.e., with or without rim) on the probability of being missing from the trap at the end of the trial. I accounted for the presence or absence of a predator exclosure by systematically including the variable in all models. Snout–vent length (SVL) was added to models if it was significant at $\alpha = 0.10$ in univariate logistic regressions (Type III log-likelihood ratio statistic, SAS Institute Inc.

TABLE 1. Mean snout–vent length ± SD and percentage of amphibians missing from pitfall traps, with and without rims, placed inside and outside a predator exclosure. Numbers in parentheses denote the total number of individuals tested in each category. A † identifies trials conducted in 1998 and 1999, whereas * identifies trials conducted in 2001.

Species	SVL ± SD (cm)	Percentage of animals missing					
		No exclosure†		Exclosure*		Totals	
		No rim	Rim	No rim	Rim	No rim	Rim
Bufo americanus	4.07 ± 1.01	0 (7)	0 (7)	0 (2)	0 (3)	0 (9)	0 (10)
Rana clamitans	4.18 ± 0.99	46.7 (30)	22.2 (36)	42.9 (21)	38.5 (26)	45.1 (51)	29.0 (62)
Rana sylvatica	4.24 ± 0.82	82.4 (17)	80.0 (15)	33.3 (9)	50.0 (12)	65.4 (26)	66.7 (27)
Ambystoma laterale	5.06 ± 1.02	83.3 (6)	80.0 (5)	100 (6)	40.0 (5)	91.7 (12)	60.0 (10)
Ambystoma maculatum	5.58 ± 1.64	71.4 (14)	10.5 (19)	11.1 (9)	0 (7)	47.8 (23)	7.7 (26)

1993). In this experiment, the absence of an individual from a trap could be due either to escape or predation. Although predation was improbable in the exclosure, some amphibians may have been predated in traps outside the exclosure. To elucidate the possible effect of predation on my results, I evaluated whether trends were similar within and outside the exclosure by testing the effect of the interaction of trap type and trap location (i.e., inside or outside the exclosure) on the probability of an individual being missing from a trap. All analyses were performed with the GENMOD procedure of SAS version 8.01 (SAS Institute Inc. 1993) at $\alpha = 0.05$.

For three out of the five species tested (*Ambystoma maculatum*, *A. laterale*, and *Rana clamitans*), a lower percentage of animals was found to be missing from traps with rims (relative to those without rims), at the end of the four-day period (Table 1); however, the relationship was significant only for spotted salamanders (*A. maculatum*; Table 2). All American toads (*Bufo americanus*) remained in the pitfall traps, regardless of snout–vent length, trap type, or trap placement (i.e., inside or outside exclosure).

In two of the five species, the probability of being missing from the trap depended on the size of individuals (Table 2). Larger green frogs (*R. clamitans*) had a greater chance of being absent from pitfall traps, whereas the presence of rims on traps slightly decreased the probability of absence (log-likelihood ratio statistic = 3.34, df = 1, $P = 0.068$). Smaller wood frogs (*R. sylvatica*) had a greater chance of being absent from traps, and the presence of rims had no effect on the probability of individuals being absent from traps after the four-day period. Furthermore, wood frogs were more likely to be missing from traps outside the exclosure than within (Table 2).

Spotted salamanders were more likely to be missing from traps without rims, and from traps placed outside of the exclosure. The probability of absence of blue-spotted salamanders (*A. laterale*) from traps was independent of snout–vent length and trap location, but the absence of rims slightly increased the chance of being absent from traps (log-likelihood ratio statistic = 3.28, df = 1, $P = 0.070$).

I did not find any significant interaction between trap type and location across all species. Despite the greater number of absences of wood frogs and spotted salamanders outside the predator exclosure (i.e., possibly due to predation in the traps outside the exclosure), these were independent of trap type. This suggests that if predation occurred in traps outside the exclosure, both trap types were similarly predated. Thus, predation cannot explain differences in the effectiveness of different trap types at retaining amphibians.

Variations in trap effectiveness can arise from different physical or behavioral characteristics across species. For example, American toads are stout-bodied and apparently unable to leap or climb out of pitfalls. In this study, small wood frogs apparently could climb out of traps with rims, whereas green frogs showed a different pattern, with larger individuals remaining less often in traps with rims. Furthermore, some species may selectively remain in pitfall traps with water (e.g., *Rana pipiens*: Shields 1985). By contrast, Brown (1997) observed that escape rates of *Bufo bufo* from pitfall traps (15 h after toad introduction into traps) were independent of trap depth (21, 28, and 40 cm) and the presence of water. Vogt and Hine (1982) observed higher frog and toad capture rates in 7.6-L traps with funnels than in traps without funnels. They also reported the occurrence of adult green frogs escaping from 7.6-L traps without funnels, but not from those with funnels.

With traps checked every four days, the use of rims improved the efficiency of pitfall traps for spotted salamanders, and to a lesser extent, green frogs and blue-spotted salamanders. For American toads and wood frogs, the presence of rims did not affect the efficacy of pitfall traps at retaining captured individuals. Further-

TABLE 2. Effect of trap type on the probability of absence of captured amphibians in pitfall traps. Parameter estimates of multivariate logistic regression models are shown with ± 1 standard error. Dashed line indicates that SVL was not included in final multivariate model. Trap type (2 levels, traps with rims as reference level) and exclosure (2 levels, traps in exclosure as reference level) are categorical variables. Significance of estimates is based on type III log-likelihood ratio statistics at $\alpha = 0.05$. No toads were missing from traps regardless of trap type or location (inside or outside exclosure), thus the models could not be computed for the species (i.e., perfect classification: Hosmer and Lemeshow 1989). The ** designate $P < 0.01$ and *** designate $P < 0.001$.

Species	N	Trap type	SVL	Exclosure
Bufo americanus	19	n/a	n/a	n/a
Rana clamitans	113	0.751 ± 0.415	0.619 ± 0.249**	−0.430 ± 0.419
Rana sylvatica	53	−0.713 ± 0.722	−1.525 ± 0.605**	1.767 ± 0.715**
Ambystoma laterale	22	2.022 ± 1.239	—	0.611 ± 1.120
Ambystoma maculatum	49	3.091 ± 0.944***	—	3.052 ± 1.198**

more, small wood frogs were more likely to leave traps than larger individuals, whereas smaller green frogs remained more often in the traps than larger individuals. Rims can prevent the escape of amphibians from pitfall traps but their efficiency will depend on the species, and in some cases, the size of the individuals. Based on these results, I suggest caution be used when comparing capture rates between species. Nonetheless, adding rims to pitfall traps is an easy way to improve trap effectiveness for certain species of amphibians. I recommend further investigations on the influence of the frequency of visits to traps on escape rates, and the differences in predation of captured amphibians in traps of different design.

Acknowledgments.—I thank É. Tremblay for granting permission to conduct this experiment in Kouchibouguac National Park. H. Frouin, A. Tousignant, and M. Huot assisted in the capture of amphibians. J. Bourque, K. Oseen, V. St-Louis, and S. Marks provided comments on the manuscript. Financial support was provided by the Ecosystem Science Fund of Parks Canada, Atlantic Region, the Wildlife Trust Fund of New Brunswick, the National Sciences and Engineering Research Council, and the Fonds pour la Formation de Chercheurs et l'Aide à la Recherche.

Determining differences in methods of reptile collection is essential in order to compare data from different studies. *A priori* knowledge of biases in techniques can be helpful for selecting capture methods appropriate to the target species. Because of the diverse natural history of snakes, it is difficult to outline procedures that are effective for each species (Fitch 1987; Gibbons 1988). Thus, multiple sampling techniques should be used in order to sample all species, sexes, and size classes within a given area (Campbell and Christman 1982; Dodd 1991; Karns 1986; Vogt and Hine 1982). Several types of direct sampling techniques have been used for snake surveys. Two of the most common collection methods are line transects and artificial covers (Fitch 1987). Our study set out to determine the effectiveness of these two methods for the capture of snakes in grassland habitats.

Line transect (LT) searches for snakes have been successfully used in a variety of habitats since the 1930's (Burnham et al. 1980). Several snake studies have used LT as the primary means of capture (Carpenter 1952; Gregory and Nelson 1991; Lacki 1994; Sullivan 1981, 2000), while others have used LT in conjunction with other techniques (Freedman and Catling 1978; Scott et al. 1989; Seibert and Hagen 1947). Advantages to using LT include increased detection of arboreal species, repeatability, and minimal expense. One major disadvantage is that the probability of detection abruptly diminishes away from the middle of a transect, an important limitation when sampling a ground dwelling species in a tallgrass situation (Burnham et al. 1980).

Artificial covers (AC) are an accepted method for collection, but few studies have employed them as the primary means of capture. AC have several benefits including low animal mortality, minimal maintenance, and can be constructed from a variety of materials such as wood, (DeGraaf and Yamanski 1992; Jensen 1968; Monti et al. 2000; Rice et al. 1994), metal (Tietje and Vreeland 1997), plastic (Engelstoft and Ovaska 2000) or a combination of materials (Adams et al. 1999; Fitch 1992; Grant et al. 1992; Parmelee and Fitch 1995).

TABLE 1. Snake species surveyed by capture method at the Prairie Ridge State Natural Area in 1999 and 2000. Only three species (*T. sirtalis*, *L. calligaster*, and *C. constrictor*) were captured in large enough numbers for statistical calculations.

	Total Captures				Weight (g)			
	Covers		Transects		Covers	Transects	K-W Test	
	N	% of Total	N	% of Total	Mean ± SE	Mean ± SE	Z	*P*
T. sirtalis	345	60.8	65	11.5	105 ± 4	104 ± 12	0.31	0.79
L. calligaster	38	6.7	80	14.1	196 ± 36	440 ± 24	5.1	< 0.0001
C. constrictor	24	4.2	10	1.8	252 ± 53	461 ± 97	2.0	0.04
Nerodia sipedon	0	0.0	3	0.5	—	—	—	—
Opheodrys aestivus	0	0.0	1	0.2	—	—	—	—
Storeria dekayi	1	0.2	0	0.0	—	—	—	—

We examined the capture rates of AC and LT for snakes at Prairie Ridge State Natural Area (PRSNA) from 1 April to 10 August 1999 and 2000. PRSNA is an 800 ha tallgrass restoration in Jasper County, Illinois, USA. We surveyed a total of 12 different grassland areas at PRSNA. Of these areas, 11 were surveyed in 1999 and 10 in 2000. Straight line transects were random within the sampling areas, and the transect length was dependent on field size. LT were performed 4–5 d/wk in all weather conditions. We abandoned LT on 25 June of each year because search efforts yielded few captures. Artificial covers were 0.6 x 3.0 m sheets of corrugated metal (barn siding or roofing) placed *in situ* four months prior to the start of data collection (January of each year) as recommended by Grant et al. (1992) and left in place for the duration of the study. Artificial covers were arranged in groups of four sheets. Fourteen groups (56 covers) were utilized in 1999 and 18 groups (72 covers) in 2000. Covers were checked every 5–7 days. Each capture was given a scale clip for future identification. In order to decrease handling time, a random sample of snakes from all grassland tracts were weighed to the nearest gram. To maintain sample independence, recaptures were not used in statistical analyses if the individual was captured more than once using the same technique. Individuals were immediately released under the AC or place of capture along the LT. The mean weights of individuals were compared between the two methods using Kruskal-Wallis tests. Because there is no way to standardize effort between the two methods, direct comparisons of capture efficiency were not evaluated.

To determine if capture rates were affected by temperature or precipitation, we used climate data collected by the Illinois State Water Survey (Station: Newton 6 SSE. ID: 116159). Mann-Whitney *U*-tests were used to compare capture rates on days with and without precipitation. We also tested the influence of the

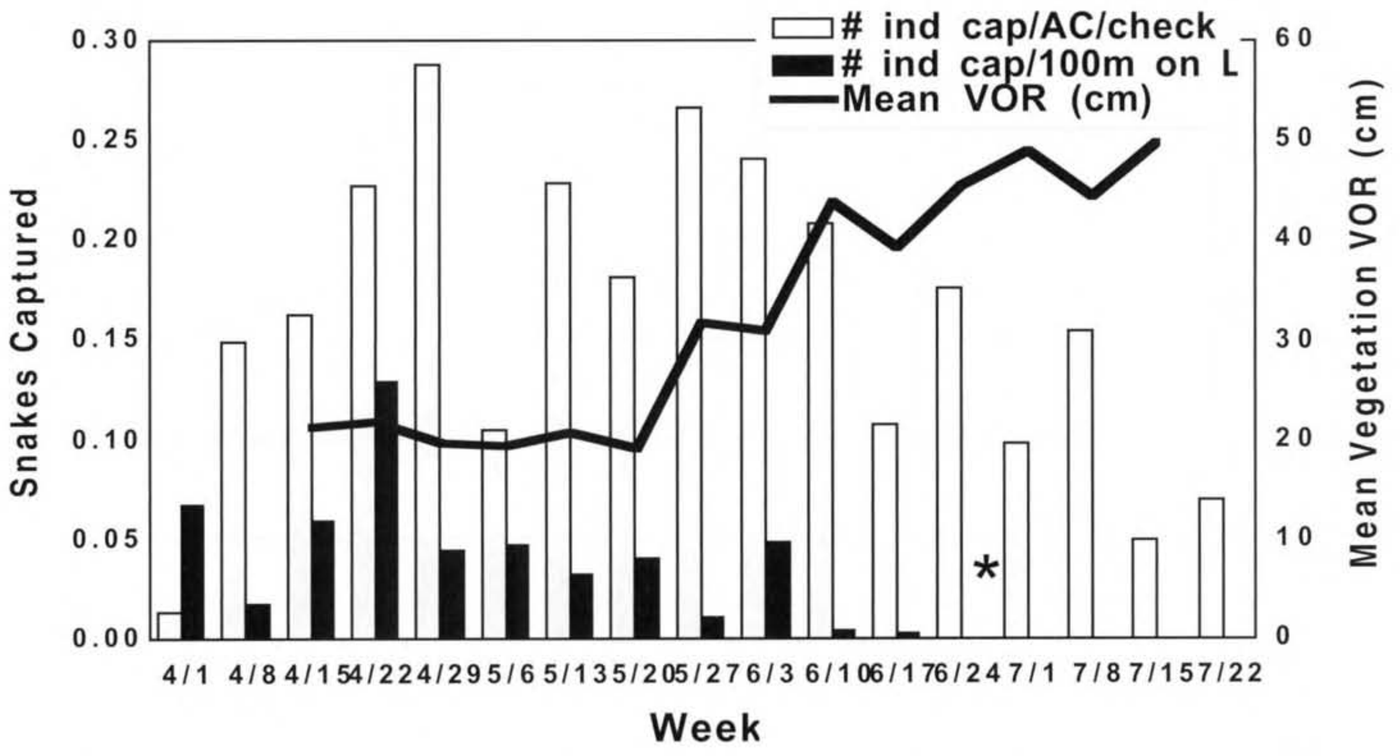

FIG. 1. Capture rates of snakes at Prairie Ridge State Natural Area in Jasper Co. Illinois, USA in 1999 and 2000 using artificial covers (AC) and line transects (LT). * Transects completed by 25 June each year.

amount of precipitation on capture rates using Spearman's rank correlation. In addition, we used Kruskal-Wallis tests to evaluate capture rates in relation to mean daily temperature. For this, we grouped the mean daily temperatures into five-degree intervals (0–30ºC).

A total of 197 random points of vegetation within the sampling areas were measured using a Robel Pole over both years. This method allowed us to record Visual Obstruction Readings (VOR) throughout the sampling period. Visual obstruction is a correlate of height and density of vegetation around a central point (Robel et al. 1970). Points were pooled and a weekly average VOR for PRSNA was calculated (Fig. 1).

A total of 567 captures of six species of snakes (Table 1) were made in 2644 AC checks (Mean = 0.15 individuals captured/AC/check) and 372.4 km searched along LT (Mean = 0.04 individuals were captured/100 m). The majority of captures (71.9%) were from covers, while 28.1% were collected along LT. Eighty-four individuals were recaptured. The common garter (*Thamnophis s. sirtalis*), prairie kingsnake (*Lampropeltis c. calligaster*), and racer (*Coluber constrictor foxii*) account for 97% of the individuals captured. Two species observed on LT were not observed under AC (Table 1).

Thamnophis sirtalis and *C. constrictor* were captured more often using AC (Table 1). The majority of *T. sirtalis* captures (82.3%) were under AC, while 70.6% of *C. constrictor* were found under AC. Conversely, 67.8% of *L. calligaster* were found on LT. Four of five individuals of additional species at PRSNA were collected via LT (Table 1).

An average VOR was calculated by pooling vegetation points from all grassland tracts. This average shows that a decrease in LT capture rates occurred when vegetation VOR increased to approximately 30 cm (Fig. 1). Transects were an efficient method of capture in early spring (15–30 April), but decreased in May when vegetation attained a VOR of 30 to 35 cm. At a VOR > 30 cm the searchers field of view is greatly diminished. However, AC produced a higher capture rate over the sampling period and remained a reliable source of captures until July when a decrease in capture rate occurred, likely in response to the rapid and extreme heating of AC (Fig. 1). We also noted that snakes would not use AC when the temperature under the cover was > 24°C. When covers were removed in November, *T. sirtalis* were utilizing them. Although weekly fluctuations in the capture rate of AC were observed, we did not find that mean daily temperature or precipitation were factors in the fluctuations. Conversely, we found the highest capture rates on LT early in the season when temperatures were 0–5°C. We attribute high capture rates during this period to low vegetation VOR, and to high concentrations of snakes as they left hibernacula, not to cooler temperatures.

We determined that species abundance and diversity was dependant on capture methodology. Certain snake species were captured more often using one particular method. For example, if only LT results are presented, the most abundant species is *L. calligaster*, whereas *T. sirtalis* would dominate if only AC information was given (Table 1). We also determined that species diversity was compromised when results from only one method were presented. Specifically, if only the AC data were given, the species composition at PRSNA would be under-represented by two species. Combining the results from both methods may be a better indicator of species abundance and diversity.

When we compared the weights of snakes between the two trapping methods, *C. constrictor* and *L. calligaster* were found to be significantly larger on LT than under AC (Table 1). This result is similar to Kjoss and Litvaitis (2001), who found smaller individuals (weight and snout–vent length [SVL]) captured under AC than in pitfall traps. In our study, *T. sirtalis* exhibited no size related differences between the two methods, suggesting that all size classes would be represented using either method for this particular species. Our results are different from a similar study of *Thamnophis* spp. by Gregory (1984) in which snakes captured under cover objects had a significantly smaller SVL than snakes found using visual surveys. One explanation as to why smaller individuals were captured under AC might be that larger individuals were easier to detect along transects. However, easier detection is arguable because there was no difference in weight between the two methods for *T. sirtalis*. A more plausible explanation is that age, sex and reproductive conditions can dictate thermal preferences (Lillywhite 1987) that influence the selection of microhabitats. Because snake body size may be correlated with survivorship, mating success, reproductive output (Gregory and Prelypchan 1994), diet (Mushinsky 1987; Rosen 1991) and age (Halliday and Verrell 1988), using a single capture method may exclude pertinent data needed for life history investigations, thereby biasing demographic studies.

Both methods examined here have problematic qualities. As we have shown, the capture rates along line transects in grasslands can vary with the density of vegetation. Additionally, artificial cover may be creating habitat that is not readily available at PRSNA therefore elevating capture rates with AC. Despite this, our findings stress the importance of including multiple collection techniques for studies of species diversity, and life history.

Acknowledgments.—This study was completed under the Illinois Department of Natural Resources (IDNR) possession of endangered or threatened species permit No. 98 – 7S and the Illinois Nature Preserves Commission special use permit. We acknowledge the Illinois Council on Food and Agricultural Research (C-FAR) and the IDNR Small Wildlife Preservation Grants for financial assistance. We thank Eric Kershner, Jeff Walk, Nisa Tawjareon and numerous field assistants for cooperation in capturing snakes and supplying data on vegetation measurements. We also thank Scott Simpson and Terry Esker (IDNR), the Illinois Nature Preserves Commission, the Nature Conservancy of Illinois, and the IDNR for access to Prairie Ridge State Natural Area.

A challenge of conducting research on population dynamics of amphibians is the selection of a suitable marking technique (Hecnar and McClosekey 1996; Ott and Scott 1999). Permanently marking individual anurans is especially difficult relative to other vertebrates because of their small size and sensitive skin (Heyer and Donnelly 1994). To date, there is no technique that satisfies all criteria for ideal individual identification set out by Ferner (1979) (Table 1). Recently, passive integrated transponder (PIT) tags have been used to permanently mark anurans (Faber 1997; Jehle and Hodl 1998; for full review of technology see Camper and Dixon 1988), however all reported techniques require anesthesia or a permanent sealant (i.e., VET Seal, super glue, suture).

For most anuran species on which PIT tagging has been applied, long-term field data are lacking (Marsh and Trenham 2000), due in part to the relative novelty (c. 1979) of the technology. Jehle and Hodl (1998) implanted tags into spade-foot toads (*Pelobates fuscus*) over an eight-year period; however individuals were transported 1 km from the study pond to a laboratory, anesthetized with MS-222, and had the PIT tag injected into the subcutaneous lateral lymph sacs with a hypodermic needle. Toads

TABLE 1. Methods for marking anurans relative to criteria set out by Ferner (1979) for ideal individual identification.

	Invasiveness	Practicality	Cost	Permanence	Reference
Toe-clipping	High	High	Low	Medium	Clarke 1972, Ferner 1979, Heyer and Donnelly 1994, Ott and Scott 1999
Tattooing	High	Low	Medium	Low	Brown 1997, Ferner 1979, Nace 1982
Cold Branding	High	Low	High	Low	Brown 1997, Farrell and Johnson 1973
Chemical Branding	High	Low	Medium	Medium	Ferner 1979, Nace et al. 1974
Skin Graphs	High	Low	High	High	Verhoeff-de-Fremery and Vervoordeldark 1982
Elastomers / Wire	High	Medium	Low	Medium	Brown 1997, Ferner 1979, Heyer and Donnelly 1994
Knee-tagging	High	Medium	Low	Medium	Elmberg 1989
PIT Tags – anesthesia	High	Low	High	High	Brown 1997, Camper and Dixon 1988, Faber 1997, Jehle and Hodl 1998, Ott and Scott 1999

were released at the point of original capture some hours later. No methods incorporating PIT tags for anurans have been reported which do not require the animals to be transported away from the study site and anesthetized (Brown 1997; Faber 1997; Jehle and Hodl 1998). In this paper we describe an effective PIT tag technique for anurans (> 40 g or > 75 mm) that can be applied in the field in less than ten minutes.

Pilot Study.—On 4 June 2001, we injected two green frogs (*Rana clamitans*) and two northern leopard frogs (*Rana pipiens*) with PIT tags subcutaneously without the use of anesthetics. Frogs received a light swab (< 0.5 ml) of 70% ethanol directly on the potential injection site (ventral side, posterior to center). This served to dry the skin and to sterilize the site. The skin was pinched with a forefinger and thumb and lifted ~4 mm away from the body cavity wall. Using a 12-gauge hypodermic needle (AVID Marketing, Inc., Norco, California; after Faber 1997), a PIT tag was injected into the flap of extended skin. No VET SEAL (after Faber 1997), or suture was required to dress the wound. Ethanol was reapplied with a sterile swab. Frogs were housed in 30 x 20 x 15 cm glass aquaria with available exposed substrate and open water. One leopard frog suffered light bleeding, most likely due to needle contact with the sub-dermal tissue. Bleeding stopped within 3 minutes. All tags migrated toward the posterior lymph space between the hind legs. The skin adhered immediately and the wound was completely healed in 9 days. Animals were observed continuously for 12 h post injection and no behavioral or physiological stress was apparent. Individuals were observed swimming and basking through the acute 12-hour post injection period. All frogs actively foraged for live grasshoppers provided by researchers 4 h post injection. Prior to the study, the two *R. pipiens* weighed 42 g and 48 g and the two *R. clamitans* weighed 59 g and 81 g; all frogs gained weight and no tags were lost during the two weeks that they were housed in the laboratory.

Field Study.—From June to August 2001 and May to August 2002, we tagged and monitored 550 bullfrogs (*Rana catesbeiana*) from four sites on the Pigeon Lake river system, near Bobcaygeon, Ontario, Canada (44.5N – 78.5W). Bullfrogs were sampled from canoe for 75 nights between 2200 and 0300 h. While one researcher held the frog ventral side up, the other implanted the PIT tag as described above. Manual manipulation of the injected PIT tag into the desired subcutaneous position (posterior lymph space between the hind legs) was required for less than 5% of the frogs. Individual frogs were tagged (and several measurements taken) in less than 10 minutes. No animals were released when bleeding. Individuals were observed for 5 minutes in a bucket post implantation, and then released at the exact point of original capture. Adult males were observed calling less than 30 seconds after release.

From June to August 2001, 65 frogs were recaptured, and from May to August 2002 an additional 150 frogs were recaptured. Ten frogs from known locations were recaptured several times. PIT tags in all recaptured bullfrogs were located in the posterior lymph space where they first migrated post-injection, although researcher handling sometimes caused the tag to move around the ventral subcutaneous space. All wounds had healed and no necrosis at wound sites was observed. Individual identification was easily made with an associated field scanner (AVID Marketing, Inc., Norco, California).

The PIT tag technique described here best satisfies the criteria set out by Ferner (1979) for ideal individual identification. PIT tagging provides a powerful tool to identify medium-to-large sized ranids for indefinite periods of time (AVID microchips have a 25 year warranty, ca. 15 years longer than the longest lived ranid). The practicality of this technique in the field has obvious benefits becasue animals are handled briefly and there is minimal equipment required. Unfortunately, PIT tagging is relatively expensive compared to other methods (each tag costs ca. US $8.00; field scanner ca. US $1000). However, minimal physiological and physical disturbance to the animal, combined with field practicality and longevity of the mark, makes this technique the most suitable and valuable reported to date.

Acknowledgments.—The Ontario Ministry of Natural Resources and The Richard Ivy Foundation funded this research. Permits were obtained from the Animal Care Committee at Trent University, which also housed the frogs involved in the pilot study. Field research was conducted from the James McLean Oliver Research Centre, Trent University. Special thanks to Magda Havas and Joe Cebek for careful review of the manuscript.

Toe-clipping of amphibians for identification and DNA collection may have minimal impact on individuals in certain cases (Gelder and Strijbosch 1996) but has also been shown to result in decreased weight gain (Davis and Ovaska 2001), infection (Golay and Durrer 1994; Lemekert 1996), reduced breeding opportunities (Lemekert 1996), and decreased recapture rate indicating increased mortality (Clarke 1972). Genetic data are becoming important not only in determining the phylogeny of amphibian species, but also for examining population history (Bos and Sites 2001), hybridization (Arntzen 2001; Carpenter et al. 2001; Highton 1998), population structure (Newman and Squire 2001; Rowe et al. 2000, Shaffer et al. 2000), and estimating number of breeding adults in populations (Driscoll 1999; Scribner et al. 1997). These studies often involve multiple samples from sensitive species and populations; as amphibian populations around the world are declining (Houlahan et al. 2000), minimizing researcher impact to amphibian populations should be a priority.

Buccal swabs have been used as an easy and non-invasive method of collecting tissue from humans for DNA extraction for many years (Thomson et al. 1992). We successfully used buccal swabs (WB10-0004; Whatman, Clifton, New Jersey, USA) to isolate workable amounts of high molecular weight DNA from barking frogs (*Eleutherodactylus augusti*). We brushed the interior of frog's mouths for approximately 30 seconds per frog and immediately placed swabs in 650 μl of lysis buffer (50 mM Tris pH 8.0, 50 mM EDTA, 50 mM sucrose, 100 mM NaCl, 1% SDS). We stored swabs at room temperature overnight before refrigerating them at 4°C until extraction. We isolated DNA using a phenol-chloroform extraction modified from Sambrook et al. (2001). Extractions began with the addition of 25 μl 10 mg/ml proteinase K followed by 55°C overnight incubation. After incubation, we washed this lysate with 650 μl phenol and then with 650 μl chloroform. We precipitated DNA by adding 0.1 volume 7.5 M sodium acetate and 0.6 volume isopropanol, followed by 0°C overnight incubation and subsequent centrifugation of samples for 30 minutes at 16,000 x g. We assessed the quality of DNA by running 4% of each sample in a 1% agarose gel and quantified using a microplate fluorescence reader (FLx800; Biotek Instruments, Inc., Winooski, Vermont, USA).

From 33 swabs of barking frogs, we isolated an average of 1 μg

high-quality DNA (95% CI 0.7 to 1.5 μg; 31.6 μg maximum) from each swab; we were unsuccessful in isolating DNA from only one swab. We also successfully extracted high molecular weight DNA from buccal swabs of bullfrogs (*Rana catesbeiana*), casque-headed frogs (*Pternohyla fodiens*), and lowland leopard frogs (*Rana yavapaiensis*).

Researchers who wish to minimize disturbance to their study populations and whose research does not require over 1 μg of DNA should consider using buccal swabs as a low-impact alternative to toe-clipping or blood collection. Also, researchers who are storing tissue samples for future studies may wish to note that we extracted high molecular weight DNA from buccal swabs that had been in lysis buffer at room temperature for 2.5 years. Toe-clips preserved in ethanol for 1–4 years also yielded high molecular weight DNA, and other researchers have extracted high molecular weight DNA from tissue preserved in ethanol for up to 10 years (Li et al. 2000). However, one set of barking frog toe-clips preserved in ethanol away from light for 5 years yielded only degraded DNA.

Acknowledgments.— Funding for this project was provided by T&E, Inc. Laboratory work was conducted in the Genomic Analysis and Technology Core at the University of Arizona. We thank Cristina Jones, Taylor Edwards, Barbara Alberti, Jim Jarchow, and J. Eric Wallace for their assistance on this project.

An Effective Technique for Collecting *Amphisbaena mertensi* with Notes on its Natural History

JENNIFER B. PRAMUK
and
HUGO ALAMILLO
The University of Kansas Natural History Museum
& Biodiversity Research Center and
Department of Ecology and Evolutionary Biology
1345 Jayhawk Boulevard, Lawrence, Kansas 66045-7561, USA
e-mail (JBP): pramuk@ku.edu

Amphisbaenians are secretive reptiles that often are difficult to collect. Because of their fossorial and elusive habits, little is known about the natural history of these reptiles; however, a few aspects of their natural history have been reported. *Amphisbaena alba* has been documented to be a facultative inquiline of the leaf-cutting ant *Atta cephalotes* (Riley et al. 1986). *Amphisbaena mertensi* has been reported to eat termites (Isoptera) and to be in high abundance near isopteran nests associated with fallen tree trunks (Neto and Abe 1993). Beebe (1945) and Duellman (1978) suggested that isopterans were the major prey type of *Amphisbaena darwinii herterozonata* from Argentina. While performing a biodiversity survey of the reptiles and amphibians in southeastern Paraguay, we obtained five individuals of *Amphisbaena mertensi* in a short period of time by using the technique described below. The behaviors, diet, measurements, and habitat conditions of the animals we collected were recorded and are reported herein.

Our findings confirm published reports of *Amphisbaena* natural history. *Amphisbaena mertensi* coexists with termites (Isoptera: Termitidae); data from stomach-content analysis of four individuals collected in southeastern Paraguay are presented below. On 28 November 2000 between 0900–1100 h, we opened 19 termite mounds in Itapúa: Alto Vera: San Pedro Mí (26°31'24"S, 55°48'19"W). The area was an active cattle pasture adjacent to remnant patches of Atlantic Forest. The region is characterized by a subhumid climate, receiving an average of 2030 mm of precipitation annually (www.atlapedia.com). We were assisted by Mr. Roberto Shulz (a local farmer and owner of one of the

FIG. 1. Photo showing the technique used to overturn 19 termite mounds underneath which five specimens of *Amphisbaena mertensi* were collected.

FIG. 2. Termite mound of *Cornitermes cumulans*.

properties we were exploring), who used the backhoe of a tractor to overturn and break open termite mounds on the pasture of his property (Fig. 1). Mr. Shulz uses this technique periodically to clear his pasture of the mounds. The active nests, constructed of hardened termite excretions (the consistency of baked clay), were difficult to penetrate with a shovel but were opened easily with the backhoe of the tractor. After mechanical upheaval and breaking of the termite nests, we used a shovel to dig and search the perimeter of the depressions left by the upturned mounds. In this manner, we excavated and explored 19 nests in 2.0 h. The nests varied in size from ca. 0.5 m to 1 m in diameter (Fig. 2). None of the specimens collected was inside the nests; instead, all specimens were found buried in the softer soil peripheral to the nests. Three of the five individuals were collected from abandoned nests that appeared to be more moist than active nests. All specimens of *Amphisbaena* were found in association with nests of the termite *Cornitermes cumulans* (Termitidae: Nasutitermitinae). Members of the subfamily Nasutitermitinae have an exclusively chemical mode of defense (Borror et al. 1989). The small mandibles of *C. cumulans* appear to pose little physical threat to amphisbaenids; this may explain why these fossorial reptiles, with soft dermal scales, are able to feed on these insects. Armadillo burrows led to some of the nests and one *Leptodactylus elenae* (Anura: Leptodactylidae; MNHNP 8691) was found in the moist space between one nest and the surrounding ground.

TABLE 1. Snout–vent length (SVL) and tail length (TL) measured (in centimeters) for five specimens of *Amphisbaena mertensi* collected in association with the termite *Cornitermes cumulans* in southeastern Paraguay. Prey items ingested by the four specimens were identified to lowest taxonomic level possible.

Specimen number	SVL	TL	Prey items
KU 290720	32.5	3.7	Ctenidae (1)
MNHNP 08740	22.1	3.4	*Cornitermes cumulans* (41)
MNHNP 08741	20.6	2.6	*Cornitermes cumulans* (15)
MNHNP 08742	30.1	4.0	Elateridae (3)

Measurements of snout–vent lengths (SVL) and tail lengths (TL) of four of the collected specimens are presented in Table 1. Average SVL and TL for these individuals was 26.5 cm and 4.3 cm, respectively. One female (MNHNP 8742), was gravid and contained six eggs; average egg volume (volume of prolate spheroid = 4/3P(length/2)(width/2)^2) of the six eggs was 1.6 cm^3. A fifth specimen was found dead in an abandoned nest. This individual had a visible wound to the head, which might have been inflicted by a predator. Because this individual was in an advanced state of decomposition, no measurements or other data were recorded; this specimen was skeletonized and deposited in The University of Kansas herpetological collection (KU 290721).

We dissected and examined the stomach contents of four specimens (MNHNP 8740–2; KU 290720) to investigate further the diets of *Amphisbaena mertensi*. To locate the stomach for dissection, we followed a published description of the soft anatomy of *A. mertensi* (Navega-Gonçalves and de Souza 2001) and made a sagittal incision along the mid-ventral portion of the body of the specimens. We then flushed the stomachs with 70% ethanol and collected their contents. Keys by Constantino (1999) and Emerson (1952) were referenced for identification of the stomach contents to the lowest possible taxonomic level.

The stomach contents of the four specimens consisted mostly of heads of *Cornitermes cumulans* and whole and partial wireworm (Coleoptera: Elateridae) larvae (Table 1). One specimen (KU 290720) had consumed an adult female spider (Araneae: Ctenidae). The remains of the large arachnid took up one-third of the volume of the specimen's stomach. Sand was present in the stomachs of all specimens examined.

Little is known of amphisbaenian natural history and behavior. To our knowledge, this is the first account of *Amphisbaena mertensi* preying on the termite *Cornitermes cumulans*. The method described above for collecting *A. mertensi* associated with termite mounds might be the most effective way of extricating these animals from the nests in a short time.

Acknowledgments.—These observations were made in conjunction with an inventory of the biodiversity of the reptile and amphibian fauna of the Atlantic Forest of southeastern Paraguay conducted by The University of Kansas and supported by the KUNHM Panorama Society and the World Bank. We thank Nancy López-Kolchaka and Marta Motte of the Museo Nacional de Historia Nacional del Paraguay for inviting us to perform our fieldwork in Paraguay. John Simmons was kind to provide assistance

in the field and the photographs presented herein. We also thank Norm Platnick, Charles Michener, and Zack Falin for helping us with identification of insects.

Biologists often require accurate measurements of some aspect of an organism's morphology (e.g., scale numbers, limb lengths, head width). Such measurements can be difficult to make in living reptiles. For instance, it may not be practical to restrain a lizard by hand while counting scales. One way to overcome this problem is to anaesthetize the animals. However, administering an accurate dose of anesthetic is crucial, but potentially problematic in small lizards. Furthermore, it may take lizards up to six hours to recover even when low dose rates of anesthetic are administered (Bennett 1991). Consequently, administering anesthetics can pose a significant health risk to small lizards (Bennett 1991). This method is also costly (50 mg/10 ml ketamine = US $45) and requires special licensing or previous experience. Alternatively, researchers sometimes euthanize lizards prior to taking measurements (e.g., Andrews et al. 2000; Melville and Swain 2000; Qualls and Andrews 1999). This technique has obvious disadvantages, such as precluding repeated measurements and, thus, the examination of the long-term effects of experimental manipulations on lizard morphology.

An ideal method would restrain living lizards for long enough to take measurements but would not harm the animals. We describe two such techniques that are suitable for restraining living lizards that span 15–100 mm snout–vent length (SVL). Our first method was developed for hatchling and adult common garden skinks *Lampropholis guichenoti* and *L. delicata*. These species range from 15 to 40 mm SVL (Cogger 2000). Our second method was developed for a series of 13 medium- to large-bodied scincid lizards from northern Queensland, Australia. These species range from 40 to 100 mm SVL. Both techniques are simple and inexpensive, and do not harm the animals.

RESTRAINING LIZARDS BETWEEN 15 AND 40 MM SVL

We placed a lizard inside a 64-ml glass jar located within an insulated box (30 x 20 cm) that was filled with crushed ice to cool the animal for 20–30 min depending on its body size (larger animals typically took longer to cool). We checked the reflexes of animals every 5 min during this time by gently poking their tail with a blunt probe. When the animal did not respond to probing, we considered it to be thermally incapacitated. At this point, we removed condensation on the skin with an absorbent tissue and transferred the lizard to a petri dish. The dish was large enough for the outstretched lizard (including its tail) to fit inside. The dish was partly covered with a rectangular strip of adhesive tape with the sticky side up (Fig. 1). The lizard was restrained by laying it on the tape. For our purposes, it was necessary to position the animal on its ventral surface. We began the positioning by adhering the head and neck of the lizard and, working posteriorly, finished with the tail. To facilitate accurate measurements of limbs

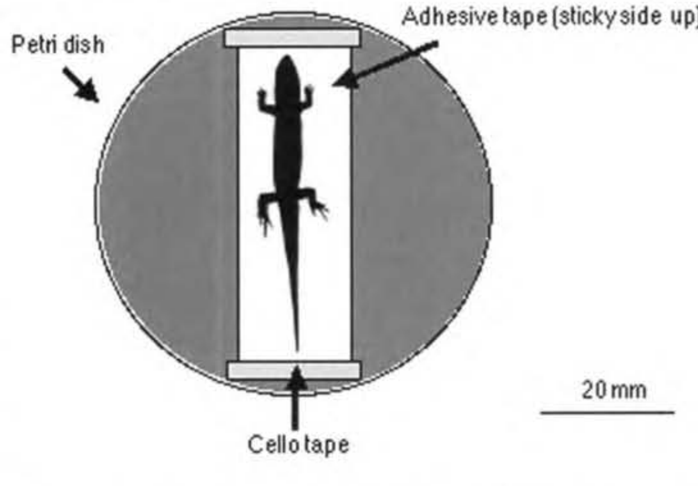

FIG. 1. Schematic of the restraint technique devised for lizards between 15 and 40 mm. The lizard is positioned within the petri dish on its ventral surface.

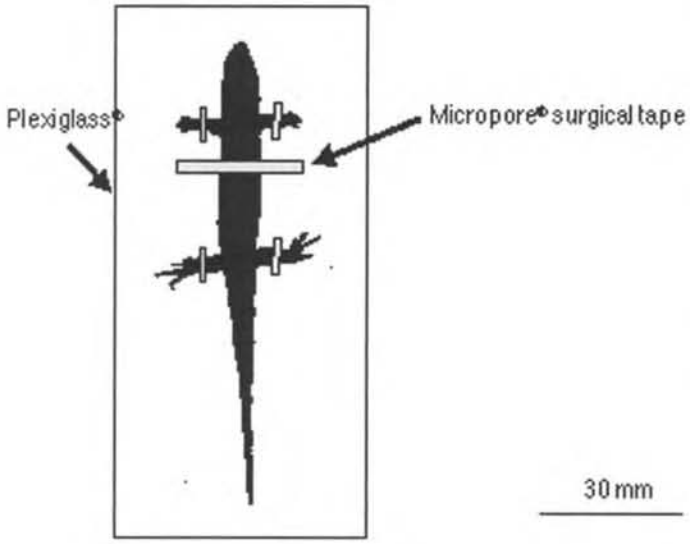

FIG. 2. Schematic of the restraint technique devised for lizards between 40 and 100 mm. The lizard is positioned on the Plexiglas® on its ventral surface.

we pressed the legs of the lizard onto the adhesive so that they were flat and in a natural, bent position (front legs ca. 120° to the body, hind legs ca. 60° to the body; Fig. 1). Fine forceps were used to spread and straighten the toes.

Although the lizards were held fast by the tape, we had no trouble removing them once our measurements had been recorded. Lizards were slowly detached from the tape, beginning with the head, and working back to the tail. Once the body was free, the tail was gently lifted from the tape by moving the body toward the tip of the tail. Lizards were always removed without ill effect and without the aid of solvents or lubricants. However, lizards other than skinks may not peel off the adhesive this easily (e.g., geckos; Bauer and Sadlier 1992). As long as the tape is free of fluids (i.e., condensation and urine), it can be reused to restrain several lizards in succession. When left to recover at room temperature (21°C), lizards typically regained activity 5–10 min after being removed from the crushed ice. This period is usually long enough to take several measurements. In some cases it may be desirable to extend the period of restraint by placing the petri dish on a bed of ice during measurement procedures.

We used this procedure to restrain > 600 *L. guichenoti* and *L. delicata* of various body sizes. Occasionally, lizards became active before completing measurements. In these cases, the lizard was placed into the glass jar and left on the crushed ice for an additional 10 min and the taping procedure was repeated. During our procedures all lizards survived and only a small proportion (< 3%, mostly hatchlings) lost the tip of their tail.

RESTRAINING LIZARDS BETWEEN 40 AND 100 MM SVL

The technique we developed for larger lizards (40–100 mm) can be used to restrain several individuals at the same time. We placed the lizards into a refrigerator set to 10–15°C. Animals were cooled for approximately 30 min, depending on their body size (larger species typically took longer to cool). Individuals were then removed from the refrigerator and placed ventral side down on a plate of Plexiglas® with their limbs outstretched. Lizards were secured to the plate using 12-mm wide strips of Micropore® surgical tape. This tape loses adhesion when wet, thus it is essential that condensation, urine, or feces on the skin of the animal be removed with an absorbent tissue prior to taping the body to the surface. We first taped lizards to the plate using a strip around the midbody and then secured the outstretched limbs (ca. 90° to the body) by placing a strip of tape over the elbow of each appendage (Fig. 2). After taking measurements, the lizards were released from the Plexiglas® plate by wetting the tape. Pulling tape off in the direction in which the scales are pointing provides the minimum amount of resistance, which is important for species that are susceptible to losing scales. Lizards were always removed without ill effect, and without the aid of solvents or lubricants.

We used this procedure to restrain approximately 300 adults of 13 species of scincid lizards. We used Plexiglas® because we radiographed animals and this material facilitates the production of low-power, high-resolution x-rays using mammogram film. However, other rigid materials also would be suitable.

We recently published the first information about age at sexual maturity for the broad-snouted caiman (*Caiman latirostris*), based on data from our captive colony (Verdade and Sarkis 1998). The present report documents a new record for the age at sexual maturity for the species. A female (CL406, Tag USP116) hatched 19 March 1996, in turn produced her first clutch on 31 December 2000. Therefore, her age at sexual maturity was approximately five years (Table 1). Clutch size was 41 eggs, all of them fertile. They were split into four artificial incubators (designed as described by Verdade et al. 1992), incubated at the following temperatures: 28°C, 30°C, 32°C, and 34°C (± 0.5°C), and monitored by StowAway® TidbiT® temperature loggers (–20° to +50°C). Incubation success at each incubation temperature is presented in Table 2.

The parents of female CL406 (sire CL1 and dam CL9) reached sexual maturity by the age of 10 years, being among the group of animals described previously (Verdade and Sarkis 1998). From age 55 days to age 430 days, female CL406 was raised in a greenhouse 16 m^2 (0.8 m^2 per individual) with cement pool ca. 4 m^2 x 60 cm deep (0.2 m^2 per individual). During the spring–summer period (October through March) she was transferred to another nearby greenhouse that offered a significant microhabitat thermal variation in such a way that either the air, the water surface, or the bottom of the pool (70 cm deep) always presented the optimum temperature for crocodilians (ca. 32°C) (as described by Fincatti and Verdade 2002). She was subsequently transferred to another enclosure 64 m^2 (ca. 2.7–10.7 m^2 per individual) with a cement pool approximately 24 m^2 x 60 cm deep (1.0–4.0 m^2 per individual), and maintained at ambient temperature. CL406 belongs to the second generation (F2) of captive bred *Caiman latirostris* in Brazil. Captive propagation of the species has been conducted in order to produce breeders for caiman farms, and thereby reducing the need for capture of individuals from remaining wild populations (Verdade 2001).

Caiman latirostris occupies a large latitudinal range, from the border between Paraíba and Rio Grande do Norte states in northeastern Brazil to southern Rio Grande do Sul at the southernmost point of Brazil (i.e., from ca. 7° to 34°S). Great variation in growth rate and age at sexual maturity can be expected for the species, as has been reported for the American alligator (Ferguson 1985). Thus, animals exposed to warmer temperatures should grow faster and attain sexual maturity earlier than individuals under cooler environmental conditions. How much of this pattern is genetically based and how much reflects phenotypic plasticity is unknown, but our report emphasizes the possible importance of temperature on the growth and reproduction of crocodilians.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 34, Number 1 (March 2003).

GYMNOPHIONA

ICHTHYOPHIS KOHTAOENSIS (Koh-Tao Caecilian). **DIET.** Oribatid mites are important decomposer animals in soils worldwide. It has been speculated that the predation pressure on these mites is low because of their strongly sclerotized cuticle (Walter and Proctor 1999. Mites. Ecology, Evolution and Behavior, Sydney, University of New South Wales Press, 322 pp.). Oribatid mites presumably live in enemy free space. However, some species have been reported in the diet of terrestrial newts like *Notophthalmus viridescens* (Norten and MacNamara 1978. J. Georgia Entomol. Soc. 11:89–93) and salamanders, e.g. *Batrachoseps attenuatus* (Maiorana 1978. Copeia 1978:664–672). Caecilians are tropical limbless amphibians inhabiting soil ecosystems (Himstedt 1996. Die Blindwühlen, Magdeburg, Westarp Wissenschaften, 160 pp). Little information is available on their dietary habits.

Food habits of *Ichthyophis kohtaoensis* were investigated during a study on the life history and ecology of this species in northeastern Thailand. Both fecal samples (3.2%) and digestive tracts (2.8%) of *Ichthyophis* contained oribatid mites (order Brachypylina). Total length of the mites varied between 0.51 and 0.69 mm (mean = 0.59 mm). The caecilians were collected during three sampling sessions during the rainy seasons from 1999 to 2001 about 15 km NE of the district town Khemmerat, Ubon Province, northeastern Thailand (16°5'N, 105°15').

These observations are the first reports of oribatid mites in the diet of caecilians. The diet of *Ichthyophis* consists mostly of earthworms, termites, and ants (Kupfer, *pers. obs.*). Because oribatid mites were only recorded in low numbers they may serve as an occasional food source.

Submitted by **ALEXANDER KUPFER**, and **MARK MARAUN**, Darmstadt University of Technology, Institute of Zoology, Schnittspahnstr. 3, D-64287 Darmstadt, Germany (e-mail kupfer@hrz3.hrz.tu-darmstadt.de and maraun@bio.tu-darmstadt.de).

CAUDATA

DESMOGNATHUS MONTICOLA (Seal Salamander). **DIET / PREY SIZE.** Seal salamanders and other plethodontids ingest exceptionally large prey items, including lepidopteran larvae and other salamanders (Krzysik 1979. Ecol. Monogr. 49:173–194; Petranka 1998. Salamanders of the United States and Canada, Smithsonian Inst. Press, Washington, DC; Bernardo 2002. Herpetol. Rev. 33:121). However, few papers report sizes of predators and prey. On 11 August 2001, in Shenandoah National Park, Virginia, USA (Research Permit: SHEN-2001-SCI-0005), we captured an adult *D. monticola* (47 mm SVL, 37 mm tail, 2.4 g) of undetermined sex at 38°17'33"N; 78°37'16"W. The capture site consisted of a first order, rocky stream within mixed hardwood forest. The abdomen of the salamander was obviously distended with a large prey item spanning the entire length of the body that was clearly visible through the ventral skin. The salamander gaped during handling thus allowing us to see part of the prey item protruding into the mouth cavity. Using forceps, we removed a lepidopteran larva (Hesperiidae; 35 mm, 0.4 g; Fig. 1) that was swallowed headfirst. Prey body length accounted for 74.5% of the predator's SVL and prey body mass accounted for 16.7% of predator's mass. The preserved lepidopteran larva and color slide of both the larva and salamander were placed in the Virginia Tech entomological collection. We thank Art Evans (Richmond, Virginia) and Eric Day (Virginia Tech) for assistance with caterpillar identification.

DESMOGNATHUS MONTICOLA (Seal Salamander). **AGGRESSION.** Aggressive behavior is widespread among plethodontid salamanders (Jaeger and Forester 1993. Herpetologica 49:163–175). Aggressive encounters for most species have been described primarily from laboratory-based or otherwise staged encounters. Observations of natural occurrences between salamanders are relatively rare. On 15 Oct 2002 I witnessed an aggressive encounter between two large male seal salamanders in a seepage area in Banks County, Georgia. The seepage had been dry most of the summer due to extended drought. However on 15 Oct, the seepage was flowing as 2.6 cm of rain had fallen during the day. Rain continued to fall steadily through the night. Just after dusk (1945 h EDT) I noticed an adult male (SVL 78 mm) that was wandering in the shallow water of the seep while he was approaching a small rocky overhang. Within 2 min I observed him again, and he had bitten, and was continuing to grip, another adult male (SVL 81 mm) that had been previously hidden by the overhang. The victim's head was almost entirely engulfed by the aggressor, the latter's snout reaching past the eyes of the former. I observed the pair again in ca. 30 min, and the aggressor was still holding the victim by the head. At this point the victim was slowly twisting over and over in an apparent attempt to escape. During intervals of rest, the aggressor attempted to pull the victim out of the water onto the bank. After watching them for several minutes, I gently placed both of them into a plastic bag. The handling did not appear to deter the aggressor, who continued his bite-hold of the victim. I checked them again in 5 min, at which time the aggressor had released the victim's head and had seized him by the middle of the tail. The aggressor held the tail for 15 min when the tail broke. I removed the victim for measuring and noticed a series of fresh bite wounds on other areas of the tail and hindquarters. After an additional 45 min, the aggressor still held the broken tail in his mouth. Within another 15 min, the aggressor had swallowed the tail. Male-male aggression is known in *D. monticola* from laboratory-based encounters (Keen and Sharp 1984. Anim. Behav. 32:58–65). However, it is unknown if this attack was male-male interference or an attempt at predation.

Submitted by **CARLOS D. CAMP**, Department of Biology, Piedmont College, PO Box 10, Demorest, Georgia 30535, USA.

DESMOGNATHUS OCOEE (Ocoee Salamander). **MORTALITY.** Appalachian streams have largely been considered to represent stable environments (Bruce 1985. Copeia 1985:847–854), and have received little attention regarding their potential as unpredictable environments for stream-dwelling salamanders. Camp (2000. Herpetol. Rev. 31:166) reported reproductive failure in a subpopulation of Ocoee salamanders (*Desmognathus ocoee*) occupying a first-order, headwater stream that had completely dried during 1999 due to drought. The site consisted of a pair of small cliffs (ca 1.5 m^2 of wet-cliff area) that prior to the drought, had permanently flowing, thin sheets of water that provided habitat for a robust population of *D. ocoee*. During summer 1994, I observed 11 different gravid females during the course of several nights of observation. During 1995, I observed 9 different females and their egg clutches. Although I did not count them, both adult males and juveniles were abundant on the cliff faces so that on a typical summer night, 30–40 metamorphosed *D. ocoee* were visible on these cliffs. Seal salamanders (*D. monticola*) were also common, but they were greatly outnumbered by *D. ocoee*. By late summer 1999, the stream appeared above ground 88 m from its earlier point of origin. That year was the beginning of a four-year drought, and this headwater stream has dried every summer since with the stream's first appearance occurring farther and farther downstream of the original point of origin. By summer 2002 many nearby second-order streams had also dried. Two tropical systems (Hanna and Isidore) and several weather fronts that passed through the area contributed 32.5 cm of rain between 14 Sept–13 Oct 2002. On 14 Oct, the first pools of above-ground water in the first-order stream were 175 m from the stream's earlier point of origin.

Beginning with the rains of Tropical Storm Hanna, I surveyed these wet cliffs and areas of the streambed for six nights (ca. 30 min/night) during significant rain events. The first survey followed three days of steady rain so that the stream was flowing and the soil was fully saturated. The number of *D. ocoee* observed ranged from 0–3/night with a total of 6–7 different individuals seen. Three were adults, and the others were subadults. No small juveniles were seen. *Desmognathus ocoee* was numerous, and all sizes of metamorphosed individuals were well represented 200+ m downstream. Even though this lower part of the stream had also dried in 2002, it had not dried in previous years, and below-ground water was probably sufficient for individual salamanders to survive in underground retreats. Because intermediate parts of the stream dried first, salamanders at the headwater were probably trapped and unable to migrate downstream. I observed a number of Ocoee salamanders occupying moist crevices in 1999 even though the cliffs were dry. This information suggests that the subpopulation occupying the wet cliffs and adjacent streambed suffered severe mortality due to desiccation.

During the same period of 2002 surveys, I observed 5–9 seal salamanders (*D. monticola*) associated with the wet cliffs each night. Because desiccation tolerance is directly related to body size in desmognathines (Houck and Bellis 1972. J. Herpetol. 6:209–215), the larger body size of *D. monticola* probably accounts for the greater survival rate in this species. I observed no small juveniles, possibly indicating that small *D. monticola* also suffered desiccation-induced mortality.

Submitted by **CARLOS D. CAMP**, Department of Biology, Piedmont College, PO Box 10, Demorest, Georgia 30535, USA.

DICAMPTODON COPEI (Cope's Giant Salamander). **REPRODUCTION.** We describe herein the discovery of two clutches of *Dicamptodon copei* eggs and their surrounding habitats in headwater streams of the Cascadae Mountains in Skamania County, Washington. The first clutch was discovered on 22 June 1998 at an elevation of ca 450 m and contained 23 eggs attached to the underside of a large basketball-sized cobble. The nest was attended by an adult female (75.6 mm standard length [SL, snout tip to posterior end of vent], Collection of Vertebrates, Department of Biology, University of Texas at Arlington, UTA-A 55076). The stream was located in a regenerating Douglas-fir (*Psuedotsuga menziesii*) plantation 18 years of age. A 2-m length of stream that contained the nest was 0.76 m wide, averaged 4.5 cm deep, had a gradient of 8°, and 93.5% canopy cover. The second clutch of eggs was discovered on 28 June 1998 at an elevation of ca 750 m and

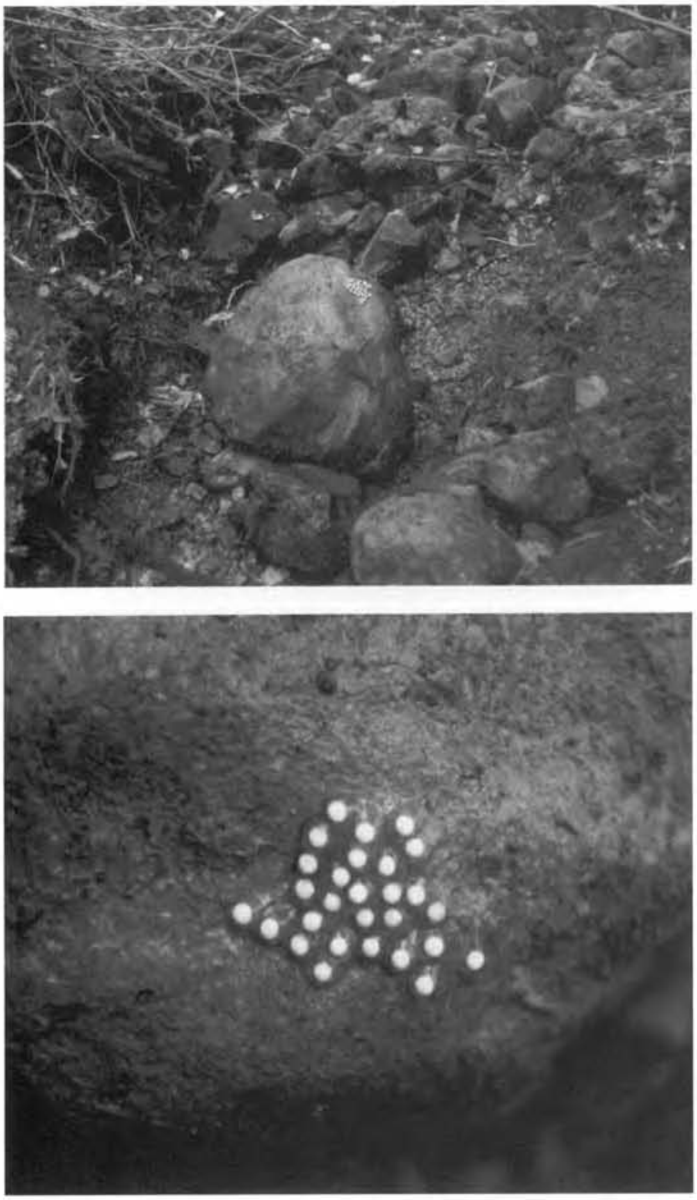

FIG. 1. Boulder on which *Dicamptodon copei* eggs were attached and a close up of the clutch.

contained 28 eggs attached the underside of a small boulder (Fig. 1). An adult female (SL 77.7 mm; UTA-A 55077) was attending the nest. The stream was located in a Douglas-fir (*Psuedotsuga menziesii*) plantation 28 years of age and had a temperature of 8.3°C. The 2-m section of stream that contained the clutch was 1.0 m wide, averaged 3.3 cm deep, had a gradient of 20°, and 92.7% canopy cover. In both cases the clutches were deposited in positions similar to that described for *Dicamptodon tenebrosus* but contained fewer eggs than generally reported for *D. tenebrosus* (Nussbaum 1969. Herpetologica 25:257–262).

ANURA

ACRIS CREPITANS (Northern Cricket Frog). **COMMUNAL HIBERNACULUM**. Hibernaculum use by *Acris crepitans* in the Arkansas Ozark Plateau is virtually unknown. In the southern parts of its range, this species is active year round and has two breeding seasons (Pope 1919. Copeia 74:93–98; Jameson 1950. Copeia 1950:61; Pyburn 1958. Texas J. Sci. 10:325–342). On 15 Dec 2001 we visited Jane's Creek in the vicinity of Ravenden Springs (Randolph County, Arkansas, USA). Its streambed is comprised of bedrock and gravel. The temperature was 11°C from 1235–1305 h with no wind and it was overcast. We walked three different areas along the shoreline turning rocks. The first area was a gravel embankment immediately adjacent to the stream. It rose steeply about 1.3 m above the waterline and extended about 10 m along the stream course. The second area was a gently sloping gravel area that barely rose above the water level. The third area was structurally similar to area 1 but located about 25 m from the stream, with area 2 between it and the stream. A 10 m stretch was surveyed in areas 1 and 3, while a 180 m transect was searched in area 2. We recovered 5 (33%) *A. crepitans* from the top of the bank in area 1. Seven (47%) were recovered from the bank in area 3, but only 3 (20%) were found in area 2. Eighty percent of the frogs were found hibernating in steep gravel slopes about 1 m above the waterline. All frogs were obviously lethargic. The three frogs found in area 2 were found individually, however, the frogs from the gravel embankments were aggregated. This suggests these frogs not only select steep banks for hibernacula, but also that they communally hibernate. This appears to be the first published report of communal hibernation in *A. crepitans*. Hibernation in groups may stabilize the immediate microclimate where these animals are aggregated, making their survival through the winter more likely. Irwin and Lee (1999. Can. J. Zool. 77:1240–1246) determined cricket frogs have a low tolerance for inundation while hibernating. Captive observations by MLM suggest that if cricket frogs are put in zip-loc bags containing water and then stored on ice or in the refrigerator, there is often significant mortality. If held in a dry bag on ice there is seldom mortality. If the investigator wishes to avoid mortality when cricket frogs are stored on ice, it would be advisable not to add water to the bags containing these frogs. Our field observations suggest that habitat management for *A. crepitans* should include bank management practices that provide hibernacula at least 1 m above the stream. This observation is particularly important considering the continual gravel mining and bank stabilization methods throughout much of the country. If gravel is removed or its height above the water surface is significantly lowered, it could cause significant population declines in this species along gravel streams. Throughout the northern cricket frog's range, if bank stabilization practices change the water content of the bank soils, reduce the availability of cracks and crevices, or drop the bank's height low enough to allow frequent inundation, this species could quickly experience dramatic declines.

Submitted by **MALCOLM L. McCALLUM,** Environmental Sciences Ph.D. Program, P.O. Box 847, Arkansas State University, State University, Arkansas 72467, USA, and **STANLEY E. TRAUTH,** Department of Biological Sciences, P.O. Box 599, Arkansas State University, State University, Arkansas 72467, USA.

BUFO NELSONI (Amargosa Toad). **PREDATION**. Reports of predation by ranid frogs on adult toads of the genus *Bufo* are extremely rare (Pearl and Hayes 2002. Amer. Midl. Nat. 147:145–152; but see Smith and Green 2002. Herpetol. Rev. 33:125). For the first time, we document predation of adult *Bufo nelsoni* by non-native bullfrogs (*Rana catesbeiana*). To our knowledge, these observations represent the largest toads that have been reported as prey to ranid frogs—at least in North America.

We used radio telemetry to study habitat use of adult *B. nelsoni* in the Oasis Valley, Nye County, Nevada, USA (UTM 0522204 E, 4083053N; Zone 11S, WGS84). On 25 March 2002, we determined that a radio signal was emanating from a bullfrog (ca. 175 mm SVL), suggesting that the frog had consumed the adult *B. nelsoni* which we were tracking. On 27 March 2002, the bullfrog was captured, euthanized, and its stomach dissected to verify the presence of a partially digested gravid female toad (87 mm SVL). The bullfrog was apparently not negatively affected by ingesting the toad as the frog escaped our initial capture attempt and then eluded capture for two additional days. Indeed, it is possible that the toad was consumed as many as 11 days prior to the capture of the bullfrog (the last time the toad was visually located). However, we cannot conclude that there were no negative effects of consuming a toad on the bullfrog as we euthanized the frog before we could rule out negative effects. Bullfrogs with SVL $\geq$ 175 mm are not uncommon in Oasis Valley, especially in areas with permanent water and dense vegetation.

At a nearby site, on 13 May 2002, Kara Vick captured a bullfrog (ca. 185 mm), which had toad legs protruding from its mouth. We pried the frog's mouth open, and removed an adult male *B. nelsoni* (79 mm SVL). The toad was covered in mucus and somewhat disoriented, but was able to crawl away after a few minutes.

We thank Robert Espinoza for reviewing a draft of this note and Tom Maertens for assistance with fieldwork. This research was partially funded through the Nevada Biodiversity Initiative and permitted by the Nevada Division of Wildlife.

RICHARD TRACY**, Biological Resources Research Center MS 314, University of Nevada, Reno, Reno, Nevada 89557, USA, and **BRIAN HOBBS**, Nevada Division of Wildlife, 4747 Vegas Drive, Las Vegas, Nevada 89108, USA.

ELEUTHERODACTYLUS ANTILLENSIS (Coquí Churí). **REPRODUCTION**. *Eleutherodactylus antillensis* is a widespread and abundant species in Puerto Rico and adjacent islands on the Puerto Rico Bank, but no published records of eggs and nests exist from within the species' natural range. Here we report on 8 clutches found in nature, 7 on Guana Island, British Virgin Islands (23 Oct 1993, 17 and 20 Oct 1994, 12 Oct 1997, 14 and 23 Oct 1999, 23 Oct 2001; observed by KO and J. Caldbeck) and 1 in Puerto Rico (on 10 Aug 2002, observed by ARE). Like other species of *Eleutherodactylus*, this species has direct development and eggs are laid on land.

On Guana Island, the egg masses were on the ground in a shrub forest: 6 were under a thin (ca. 2 cm deep) layer of leaf litter, and 1 was under a grass mat. The clutch size of 6 newly laid egg masses (located by following courting pairs) ranged from 25 to 42 eggs (mean = 31, SD = 5.8); the remaining clutch (found by raking of leaves) contained 9 eggs. Newly laid eggs were round, opaque white, and were laid in a globular cluster. Individual eggs measured ca. 4–4.5 mm in diameter. The development of one clutch, followed from oviposition to hatching, took 15 days at temperatures of ca. 25–30C° at the natural location. No frog was in attendance at any of these clutches during several day- and night-time inspections.

In Puerto Rico, a clutch of *E. antillensis* with 24 eggs was found near Tetas de Cayey, Barrio Cuyón, Salinas (825 m elev). Individual eggs measured ca. 3.2–4.0 mm in diameter. The eggs were in an advanced stage of development (Stage 7 or later; Townsend and Stewart 1985. Copeia 1985:423–436), based on strong, rapid movements of the embryos. The clutch was under a small wood block (20 x 10 x 5 cm) over reddish soil, clean of vegetation, and near a house in construction. An adult male *E. antillensis* was adjacent to and in physical contact with the egg mass. The clutch and frog were held captive in a small plastic terrarium, with soil taken from the site as substrate, and were maintained at 28–32°C with relative humidity of 75–87%. The male frog sheltered under the same piece of bark where the clutch was placed but did not crouch on top of the eggs, as do males of *E. coqui* when attending eggs. Nine to 11 days after collection, the eggs hatched. The froglets measured 4–5 mm SVL. All froglets had a bicuspid egg tooth on the median margin of the upper lip; no vestigial tail was present at hatching.

Our observations indicate two features of particular interest: oviposition on the ground, rather than in vegetation or arboreal locations, and apparent absence of parental care on Guana Island. In contrast, male parental care of eggs occurs in *E. coqui* and several other Puerto Rican species of *Eleutherodactylus* (Townsend 1996. *In* Powell and Henderson [eds], Contributions to West Indian Herpetology: a Tribute to Albert Schwartz, pp. 229–239. Society for the Study of Amphibians and Reptiles. Ithaca, New York). Our observations also suggest a clutch size that is somewhat larger than reported for *E. antillensis* in captivity (11–32 eggs; Michael 1997. Herpetol. Rev. 28:141–143; Joglar 1998. Los Coquís de Puerto Rico. Su Historia Natural y Conservación. Editorial De La Universidad De Puerto Rico, San Juan, Puerto Rico) and for an introduced population within residential gardens in Panama City (11–28 eggs; mean = 19 eggs; Castillo and Mayorga 1984. Distribucion, habitos ecologicos, reproduccion y embriologia externa de *Eleutherodactylus antillensis* [Anura]. Unpubl. Thesis. Universidad de Panama [Facultad de Ciencias Naturales y Farmacia], Panama City, Panama). Whether the presence of a male frog in the vicinity of the clutch from Puerto Rico represented parental care remains enigmatic.

Support for studies on Guana Island came from the Conservation Agency through grants from the Falconwood Foundation. We thank Skip Lazell for invaluable support and Jeannine Caldbeck for assistance in the field. ARE was supported by NSF/MIE Project at Universidad Metropolitana, San Juan, Puerto Rico.

ELEUTHERODACTYLUS STEJNEGERIANUS (Stejneger's Dirt Frog). **URBAN HABITAT**. Although certain Caribbean species of *Eleutherodactylus* are notorious for thriving in urban habitats in both their native islands and in cities around the hemisphere (Kaiser 1997. Biodiv. Conserv. 6:1391–1407), within lower Central America no native *Eleutherodactylus* were previously known to occupy urban habitats. We report the widespread occurrence of *E. stejnegerianus* in the city of Escazú (Cantón Escazú, province of San José, Costa Rica), a heavily developed suburb whose human growth replaced coffee plantations and cattle pastures. *Eleutherodactylus stejnegerianus* was previously regarded as a leaf-litter species (Savage 2002. Amphibians and Reptiles of Costa Rica. Univ. Chicago Press, Chicago. 934 pp.), found only in forests. One voucher specimen (University of Costa Rica, Museum of Zoology UCR 16856) was collected 25 June 2002, at 2045 h, under the shrubs in the side yard of the house of Mr. Brian Kubicki (09°54.352'N, 83°08.530'W). Identification of the specimen was verified by Gerardo "Cachí" Chaves of the University of Costa Rica, Museum of Zoology. Two other frogs were heard calling in the yard that same night. Individuals were heard and occasionally captured at three sites within Escazú. Earlier, on 12 June at ca. 1900 h, two frogs were heard calling from a tangle of dead plants in the backyard of a condominium at 09°56.164'N, 84°08.646'W. On 24 June around 2100 h, one *E. stejnegerianus* was captured and at least three more were heard in the well-manicured backyard of a house (09°56.009'N, 83°07.077'W). These three localities were separated by 1.4–3.3 km straight line distance. At the latter two sites, *E. stejnegerianus* was heard calling most nights from the beginning of the rainy season in May though the end of August 2002, and have not been heard in the 1.5 months since then. Specimen collected under MINAE permit number 024-2002-OFAU to A. J. Crawford.

HYLA ARENICOLOR (Canyon Tree Frog). **TOXIC SKIN SECRETIONS.** Toxic or noxious skin secretions have been well documented in amphibians (Erspamer 1971. Ann. Rev. Pharmacol. 11:327–350; Michl and Kaiser 1963. Toxicon 1:175–228). Among anurans, the most well-known for their toxic skin secretions are dendrobatid frogs and bufonids (Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill, New York. 670 pp.). However, toxic skin secretions from other anurans are less well documented. *Hyla arenicolor* ranges from southwestern Colorado and southern Utah (USA) southward to Oaxaca, Mexico, and from western Texas to western Arizona (USA) (Stebbins 1985. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 336 pp.). Hammerson (1999. Amphibians and Reptiles in Colorado. University Press of Colorado, Niwot, Colorado. 484 pp.) noted that when handled, *Hyla arenicolor* usually release fluid from the vent and produce a sticky skin secretion. However, no further information or any effects of this skin secretion have been recorded. Herein, we report the effects of skin secretions of *Hyla arenicolor*, contacting the conjunctival mucosa of the eyes.

During a field-collecting trip to central Arizona, one of the authors (RLP) captured and examined several individuals of *Hyla arenicolor* consequently distributing a generous amount of frog skin secretions over his hands and fingers. Shortly afterwards, while attempting to remove dust and perspiration, the substance was accidentally introduced into both eyes by vigorous rubbing. Upon contact with the mucous membranes of the eyes, there was moderate to intense burning of the conjunctiva and marked sensitivity to sunlight. This was followed by copious amounts of mucous discharged from the nasal area that continued throughout the duration of the episode, which lasted ca. 45 minutes and then subsided rather abruptly. Approximately 15 minutes after the initial exposure, the eyes were flushed with liberal amounts of water. However, this did not seem to reduce the symptoms to any degree. Afterwards, only slight reddening of the conjunctiva was apparent, which lasted into the evening, and no discomfort or symptoms were noted the next day.

HYLA GRATIOSA (Barking Treefrog). **INTESTINAL HERNIA**. Deformities and malformations in anurans occur in a variety of manifestations (Meteyer 2000. Field Guide to Malformations of Frogs and Toads with Radiographic Interpretations. Biol. Sci. Rep., USGS/BRD/BSR-2000-0005, 18 pp.). Most of those described in the literature are visible externally (e.g., ectromelia, brachydactyly, polydactyly, brachygnathia, kyphosis) (Ouellet et al. 1997. J. Wildlife Dis. 33:95–104). Internal malformations are less well

FIG. 1. Intestinal hernia with 3 cm intestine exposed beneath the ventral skin in *Hyla gratiosa*.

known and seldom reported (Reeder et al. 1998. Environ. Health Persp. 106:261–266). Here we describe an unusual condition heretofore unreported for a hylid frog.

On 19 May 2000 we found a calling male *Hyla gratiosa* (49 mm SVL) at USMC Camp Lejeune, Onslow County, North Carolina (USA) that exhibited a ca. 1 cm diameter mass under the skin of the venter. Necropsy revealed that an ca. 3 cm loop of the intestine and the spleen had protruded though a 2.5 x 3 mm hole in the ventral mid-line of the body wall and was entrapped within the ventral lymphatic sac (Fig. 1). The intestine was moderately dilated but not obstructed. The bilateral fat bodies of this frog were severely atrophied. A filarid parasite occurred in the mesentery at the base of the lungs and stomach. Peritonitis was mild to moderate. All other internal organs were normal. This frog was one of several males in a breeding chorus in a large, isolated wetland. Its behavior was normal and it was apparently not hindered by the hernia. We suspect that the intestinal hernia was a deformity secondary to a malformation (hole) in the ventral midline. This hernia may be analogous to umbilical (i.e., yolk sac resorption site of amphibians) hernias in humans and other mammals. An intestinal hernia is an unusual deformity in frogs.

Funding for fieldwork was provided to JCM by the Legacy Resource Management Program of the U.S. Dept. of Defense.

HYLA PULCHELLA (NCN). **PREDATION.** Anuran tadpoles and froglets are common prey for a variety of invertebrates and vertebrates. On 8 Jun 2002 at 1700 h we collected four *Hyla pulchella* tadpoles at a semipermanent pond in Entre Ríos Provinces (31°31'S, 60°10'W). These *H. pulchella* tadpoles were placed in a semi-natural pond with water and plants from the collecting locality. This pond was ca. 22 x 30 cm, pH was 7, and temperature was 15°C.

Three live tadpoles (TL 27 mm, Gosner stage = 31, 32) were observed being consumed by juvenile snails, *Pomacea canaliculata* (Gastropoda, Ampullariidae) (mean shell diameter 34.5 mm). The snails were positioned 30 cm above the water on detritus, humid soil, and aquatic vegetation, holding a tadpole in the snail's aperture. The snails and tadpole prey were photographed after preservation (Fig. 1). To our knowledge, this is the first report of predation on anuran tadpoles by a snail. However, the diet of *P. canaliculata* is reported to include insects, crustaceans, and fishes (Alonso and Ageitos de Castellanos 1949. Notas del Museo de la Plata. Tomo XIV, N° 115:31–38; Estebenet 1995. The Veliger 38[4]:277–288).

FIG. 1. (a) *Hyla pulchella* tadpole being held by juvenile *Pomacea canaliculata*; (b) after predation. Bar = 15 mm.

We thank Inés Ezcurra de Drago for providing information on the biology of this snail.

Submitted by **PAOLA M. PELTZER** and **RAFAEL C. LAJMANOVICH**, National Institute of Lymnology. José Maciá 1933. (3016) Santo Tomé, Santa Fe-Argentina; e-mail: inali@ceride.gov.ar

LEPTODACTYLUS CHAQUENSIS (NCN), ***PSEUDIS PARADOXA*** (Paradox Frog), and ***PHRYNOHYAS VENULOSA*** (Veined Treefrog). **PREDATION**. Snakes are often referred to as important predators of frogs, mainly in the tropics (Vitt and Vangilder 1983. Amphibia-Reptilia 4:273–296). Nevertheless, predatory events in nature are rarely observed and published (Martins et al. 1993. Amphibia-Reptilia 14:307–309). Furthermore, among vertebrate predators of frogs, birds are generally reported preying on tadpoles (McAlpine et al. 2001. Herpetol. Rev. 32:183–184; Castanho 2001. Herpetol. Rev. 32:103). Birds that prey on adult frogs are less documented (Brodie and Nussbaum 1987. Herpetol. Rev. 18:8–9; Master 1998. Herpetol. Rev. 29:164–165). Herein I describe predation on different species of frogs by a heron and two snake species observed during fieldwork in southern Pantanal. The observations were made at Base de Estudos do Pantanal/UFMS (19°34'S, 57°00'W), municipality of Corumbá, State of Mato Grosso do Sul, southwestern Brazil.

On two occasions I observed a rufescent tiger heron, *Tigrisoma lineatum* (Ardeidae), preying upon adult frogs at the edge of ponds during the day. On 13 Nov 2000 at 1630 h, a paradox frog, *Pseudis paradoxa*, was observed being preyed upon by the heron, and half an hour later another frog, *Leptodactylus chaquensis*, was also taken. On 13 Jan 2002, another *L. chaquensis* was observed being preyed upon by the heron. In all cases the frogs were partially submerged, and the birds were motionless searching for prey in the water. The Pantanal is rich in ponds that are used as foraging sites by many species of wading birds, thus any Ciconiiformes could represent important predators of adult frogs.

On 21 Nov 1997 at 2140 h, a colubrid snake, *Clelia bicolor*, was observed constricting a juvenile *L. chaquensis* at the edge of a flooded area. On 10 Jan 2002 at 1500 h, a green parrot snake, *Leptophis ahaetulla*, was observed preying upon an adult veined treefrog (female, 77 mm SVL), *Phrynohyas venulosa*. The distress call emitted by the frog called my attention, and I found the snake on a shrub in a flooded gallery forest, about 1.0 m above the water, head-down, and holding the frog with its jaws by the lateral portion of the frog's head. The treefrog remained motionless, secreting the white glue-like skin secretion, which was already spread on the snake's snout. At 1528 h, the snake had finished ingestion of the treefrog, and upon my approach, the snake immediately released the frog, that fled away swimming. The snake disappeared climbing the shrubs and trees. The treefrog was collected to be measured, and seemed to be dying, but one hour later was in good shape, and was released near the same site. Approximately one hour later, the snake returned to exactly the same branch of the

shrub, and seemed to be looking for the lost prey.

The peculiar milky and sticky skin secretion produced by *P. venulosa* is considered to be toxic (Gallardo 1987. Anfíbios Argentinos: Guía para su Identificación. Libreria Agropecuaria S.A., Buenos Aires, Argentina. 98 pp.), and it is suggested that these secretions might have a defensive function against predators (e.g., McDiarmid 1968. Los Angeles County Mus. Contrib. Sci. 134:1–25; Duellman 1970. Monogr. Mus. Nat. Hist., Univ. Kansas [1]:xi + 753 pp.). Furthermore, the rubbery viscosity of the skin secretion was described as preventing snake predation on the veined treefrog by acting as a glue (Leary and Razafindratsita 1998. Amphibia-Reptilia 19:442–446; Manzanilla et al. 1998. Herpetol. Rev. 29:39–40). But the behavior of *L. ahaetulla* described here, returning to the same site, is evidence that this snake could be an important predator of *P. venulosa*, at least in the Pantanal, despite the frog's sticky and alleged toxic secretion. The treefrog's behavior—immobility during ingestion—could also be an important secondary defense, diminishing risks of injury and increasing the survival chance in the case of being regurgitated by the snake.

I am grateful to A. S. Abe, C. F. B. Haddad, and M. T. Hartmann for critically reading and commenting on this manuscript, and to P. Landgref, E. Amorim, and V. Berto Jr. for field assistance. I also thank Base de Estudos do Pantanal – Universidade Federal de Mato Grosso do Sul for the logistical support, and CNPq for research fellowship (proc. 521746/97–3/NV), and graduate fellowship (procs. 351228/97–7, 140397/2000–0).

LEPTODACTYLUS OCELLATUS (Rã Manteiga). **PREDATION**. On 15 October 2001 at 1035 h we observed natural predation by *Buteo magnirostris* (Roadside Hawk: Falconiformes: Acciptridae) on an adult *L. ocellatus* (Centro de Estudos e Pesquisal Biológicas - CEPB 6738 - femur: 50.8 mm; tibia: 56.6 mm; tarsus: 29.3 mm) on an unvegetated bank of the Uruguai River (27°30'02"S, 51°47'50"W), municipality of Machadinho, in the state of Rio Grande do Sul, Brazil. This observation is the first report of avian predation on *L. ocellatus*.

We thank the staff of NATURAE - Projetos e Consultoria Ambiental Ltda. in the Cotiara Faunal Rescue Operation for help during fieldwork.

Submitted by **IVAN FRANÇA E SOUZA, WILIAN VAZ SILVA, PABLO VINICIUS C. MATHIAS,** and **NELSON JORGE DA SILVA JR.**, Laboratório de Herpetologia and Laboratório de Ornitologia, Centro de Estudos e Pesquisas Biológicas, Universidade Católica de Goiás, Ave. Universitária, 1440, Setor Universitário, 74.210-010, Goiânia, Goiás, Brazil (e-mail: souzai@terra.com.br).

PHYLLOMEDUSA SAUVAGII (Painted-belly Leaf Frog) **PHYSICAL COMBAT.** *Phyllomedusa sauvagii* is one of six species that belong to the poorly-defined *tarsius* group and is one of the most distinct species of *Phyllomedusa* (Cannatella 1980. Occ. Pap. Mus. Nat. Hist. Univ. Kansas 87:1–40). On 25 Oct 2001 at 2100 h we observed an interaction between two males (SVL = 84.5 mm and 87.2 mm) in a temporary pond (Serra da Bodoquena, Assentamento Canaã, 20°41'32.3"S; 56°44'34.3"W, Bodoquena Municipality, Mato Grosso do Sul, Brazil). The smaller male was vocalizing from the top of a shrub, and the bigger male moved toward the shrub while emitting a different type of sound. The larger male climbed to the top of the shrub and within 10 sec, the two males engaged in physical combat. The movements of both males were slow as each one tried to grab the head and body of the other by flinging its arms and legs. The two clutched each other so that their bellies remained in contact, but at the same time each one was trying to extricate itself from the other. They were both suspended in the air for 10 min with only their feet clinging to the vertical stem of the shrub, while they were fighting and emitting different sounds. Finally, the larger male managed to throw off the smaller one into the pond. The larger male assumed the place on the top of the shrub where the smaller male had been and began to vocalize within 5 minutes. The two individuals were collected and deposited in the Zoological Collection at the Universidade Federal de Mato Groso do Sul (ZUFMS 0508). Although there are accounts of visual displays in this species (Halloy and Espinoza 1999–2000. Herpetol. Nat. Hist. 7:175–180) and other species of *Phyllomedusa* (*P. distincta*, Castanho, unpubl. data; *P. burmeisteri*, C. F. B. Haddad, pers. comm.), no visual displays were observed in this encounter. There is a report of territorial behavior and physical encounter between two male *P. hypochondrialis* (Matos et al. 2000. Herpetol. Rev. 31:84–86) similar to that reported here with *P. sauvagii*.

PHYSALAEMUS* CF. *FUSCOMACULATUS (NCN). **PREDATION**. Several groups of birds prey upon post-metamorphic anurans (Duellman and Trueb. 1994. Biology of Amphibians. John Hopkins Univ. Press. 670 pp.). *Physalaemus* cf. *fuscomaculatus* (Leptodactylidae) is found in open vegetation in southeastern Brazil and reproduces during the rainy season (Rossa-Feres and Jim 2001. Rev. Brasil de Zool.18:439–454). On 26 Nov 2001, in the Clube de Caça e Pesca Itororó de Uberlândia municipality, state of Minas Gerais, Brazil, we observed an adult female (bearing eggs) *P.* cf. *fuscomaculatus* (36 mm SVL) being preyed upon by a "Guira Cuckoo" (*Guira guira*; Cuculidae; Aves) (Fig. 1). The frog had the interior right portion of its mouth broken and the tongue exposed. This observation is the first report of predation of *P.* cf. *fuscomaculatus* by a bird and the second of an anuran by *G. guira*.

The specimen of *P.* cf. *fuscomaculatus* (AAG-UFU 2228) is deposited at the Museu de Biodiversidade do Cerrado, in the Universidade Federal de Uberlândia, Minas Gerais state, Brazil. We thank Ariovaldo A. Giaretta and Marcelo Menin for critically reading this mansucript.

PHYSALAEMUS NATTERERI (NCN). **PREDATION**. On 18 Oct 1995 at 2145 h after a heavy rain (98 mm in five hours) in Nova Itapirema (21°04'S, 49°32'W; 460 m elev), State of São Paulo, Brazil, a water-snake (*Helicops infrataeniatus*) in a temporary pond was observed preying on an adult *Physalaemus nattereri* during vocalization. The snake bit the prey by the head triggering the *P. nattereri* defensive deimatic strategy of inflating the body and exposing the large ocelli on its back (Sazima and Caramaschi 1986. Rev. Biol. [Lisb.]13:91–101). The snake immediately constricted the posterior part of the prey clockwise (Fig. 1). After ca. 15 min the snake uncoiled, keeping the head bitten and then dove to the bottom of the pond, where visual contact was lost. The *P. nattereri* deimatic behavior is considered more defensive than inhibitory when exposed to predators in captivity (Sazima 1973. Ci. e Cult. 25[supl.]:390), and in the event reported here, since *H. infrataeniatus* may be not a visually oriented predator. Probably in this situation, *P. nattereri* relies more on camouflage, "freezing," and in secretions from its inguinal glands (Vizotto 1964. Ci. e Cult. 16:168) as antipredator behaviors. On the other hand, some small visually oriented predators could be the operant selective agents for *P. nattereri* inhibitory behavior.

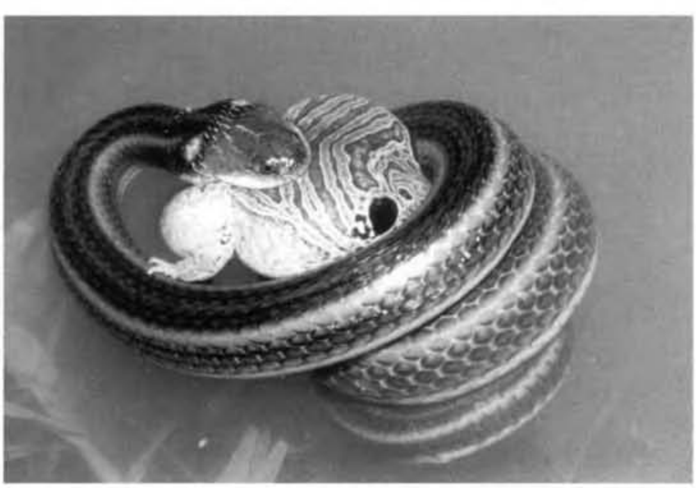

FIG. 1. *Helicops infrataeniatus* preying on *Physalaemus nattereri* (Nova Itapirema, São Paulo, Brazil).

RANA AURORA AURORA (Northern Red-legged Frog). **JUVENILE GROWTH; MALE SIZE AT MATURITY.** Among anurans, high juvenile mortality after metamorphosis often makes recapturing individuals to assess early growth and size at maturity near impossible without extensive marking efforts (Turner 1962. Quart. Rev. Biol. 37:303–314). Licht (1974. Can J. Zool. 52:613–627) minimally estimated survivorship for juvenile *R. a. aurora* from southwestern British Columbia in their first year following metamorphosis at a fairly high 52%, implying that such data might be easier to obtain for this species. Yet, the frequent rapid disappearance of juvenile *R. a. aurora* from their natal ponds (MPH, pers. obs.) and immobility anti-predator tactics (Gregory 1979. Herpetologica 35:175–184) linked to dependence on crypsis have hindered obtaining precise data. Licht (1986. Can. Field-Nat. 100:22–31) did record newly metamorphosed *R. a. aurora* in British Columbia at 28–33 mm SVL and classed frogs > 40 mm SVL as ≥ 1-year old, but this only presumes a lower bound of 7–12 mm 1st-year growth at this latitude. Thus, opportunity to frequently observe a few *R. a. aurora* in a pond in lowland western Washington State allowed us to gather preliminary data on juvenile growth and male size at maturity.

We made observations in an isolated pond (3.3 m^2 surface area; 41 cm max. depth) built in July 2001 as part of a habitat restoration effort within an altered forest matrix NW of Olympia (Thurston County), Washington (47°07'11"N; 122°56'11"W). As water percolated too rapidly through its substrate (glacial till: Hayes and Hayes, Herpetol. Rev. *in press*), a preformed 0.5-cm thick black polyethylene liner had been placed to ensure pond water levels could be maintained. The pond margin was lined with black cobble-sized basaltic rock, and we placed two pieces of wood in the pond. Of the latter, one (0.9 m long x 10 cm diam) was well decayed and sank within a few days; the other (0.5 m long x 10 cm diam), undecayed, remained floating. Mature sword ferns (*Polystichum munitum*) were planted at relatively high density (ca. 1/m^2) over about 90% of the area within 2.5 m of the pond as sword fern is thought to present a cover structure favorable to *R. a. aurora* (Kelsey 2000. *In* O'Connell et al. [eds.], Effectiveness of Riparian Management Zones in Providing Habitat for Wildlife, pp. 8.1–8.38. Final Report: Timber, Fish, and Wildlife Program, Olympia, Washington). The pond was sited within 10 m of a ≥ 80-year-old Douglas-fir (*Pseudotsuga menziesii*) stand and an infrequently traveled, one-lane paved road, and within 3 m of the porch of a two-

story dwelling from which observations could be easily made. During the May–September 2002 interval we discuss, the pond was exposed daily to morning and midday sun, and increasingly shaded thereafter. The pond had been allowed to mature over 10 months during which time it developed a micro- and meso-biota, mostly through accumulation of litterfall and visits from birds. On 4 May 2002, 7 *R. a. aurora* (33–37 mm SVL) near metamorphic climax, each with a unique toe clip mark, were placed in the pond. The source of these individuals was a small stream-associated pond in the Stillman Creek Basin (Lewis County), ca. 64 km SSW of the recipient pond (46°34'05"N; 123°10'58"W).

Of the 7 *R. a. aurora* placed in the pond on 4 May, 5 vanished during the first two months. We recaptured the remaining two frogs (here A and B) on 31 August 2002; on 4 May, these frogs measured 33.0 mm SVL and 2.3 g, and 35.5 mm SVL and 2.9 g. On 31 August (119 days later), both frogs were identified as males based on nuptial pad development and hypertrophied forearms. Male A (now 54.0 mm SVL and 12.8 g) and male B (now 55.5 mm SVL and 12.5 g) had grown at rates of 0.18 mm/dy and 0.17 mm/dy. To further ensure their future identification, we PIT-tagged both frogs before release. Both were recaptured a second time on 22 September 2002; male A was then 58.0 mm SVL and 15.7 g, and male B was 57.5 mm SVL and 15.5 g. Over this next 22-day interval, the growth rate of male A had remained unchanged at 0.18 mm/dy, but that of male B nearly halved to 0.09 mm/dy.

Our observations reveal that juvenile male *R. a. aurora* can exhibit rapid growth during their active season in the Puget Sound lowlands. Male *R. a. aurora* would be able to reach sexual maturity within the year after they develop from eggs with the growth rates we recorded. Based on limited evidence from western Oregon, Nussbaum et al. (1983. Amphibians and Reptiles of the Pacific Northwest. University Press of Idaho. 332 pp.) suggested that males reached sexual maturity around 50 mm SVL in their 2nd year after metamorphosis, and Leonard et al. (1993. Amphibians of Washington and Oregon. Seattle Audubon Society, Seattle, Washington. 168 pp.) indicated that 3 or 4 years were likely required for "froglets" (i.e., recently metamorphosed juveniles) to reach sexual maturity. The 50 mm SVL size at maturity for male *R. a. aurora* that Nussbaum et al. (*op. cit.*) proposed agrees with our findings. However, while more data are clearly required to understand how representative the growth rates we present may be, they indicate that the time required to reach sexual maturity might need reconsideration.

The Science Division of the Habitat Program of the Washington Department of Fish and Wildlife supported this research; this work represents a contribution to the Science Division's Forest and Fish Adaptive Management Program.

RANA BOYLII (Foothill Yellow-legged Frog). **OVIPOSITION BEHAVIOR**. *Rana boylii* is a medium-sized (37–71 mm SUL) frog that occurs in rivers and streams of Oregon and California (Stebbins 1985. Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 336 pp.). It is a stream breeding frog that usually attaches its eggs to underwater boulder or cobble substrates. There is little known about the reproductive ecology of this species. We describe a previously unreported oviposition behavior of *Rana boylii* in which the female frog prepares the substrate for egg mass attachment.

On 03 May 2002 we observed the oviposition behavior of an amplexing pair of *Rana boylii* at Hurdygurdy Creek in northwestern California, USA. At ca. 1100 h we observed a pair of frogs in axillary amplexus. The pair moved a short distance away from the location where first detected, which we attributed to disturbance caused by our presence. Half an hour later, the pair returned to the original site. The female, with the male still gripping her dorsal side, backed up until her hind feet were resting against a cobble (ca. 35 cm x 12 cm). The female then began scraping the surface of the cobble, loosening particles of algae and sediment that were on the surface of the rock. Scraping continued intermittently for ca. 50 minutes. Three seconds after scraping ceased, the male lowered his hind feet, resting them on the female's thighs. As the female released her eggs on the "cleaned" area of the cobble, the male occasionally rubbed his hind feet down her thighs. It appeared that the male might have been guiding the eggs into the "basket" formed by the hind limbs of the pair and the surface of the cobble. Oviposition and fertilization lasted ca. eight minutes. Following fertilization, the male lifted his hind feet off of the female's thighs. The female crawled away from the egg mass and five seconds later, the male released her.

On 11 May 2002 at ca. 1500 h we observed another amplexing pair of *Rana boylii* where the female was scraping the surface of a cobble (ca. 10 cm x 5 cm) with her hind feet in the same manner as described above. The pair moved away from the location where first detected, which we again attributed to disturbance caused by our presence. Oviposition was not observed, however, at 2100 h we returned to the study area and found a new egg mass attached to the same cobble that the female had been scraping.

Video footage of scraping and oviposition behaviors can be viewed at: http://www.rsl.psw.fs.fed.us/projects/wild/herpwebpage/rabo.html.

RANA BOYLII (Foothill Yellow-legged Frog) and ***RANA CATESBEIANA*** (Bullfrog). **REPRODUCTIVE BEHAVIOR**. Bullfrogs (*Rana catesbeiana*) were introduced into the western United States in the late 1800s. Populations continue to grow and expand into new areas both as a result of human activities and through "natural" dispersal. Bullfrogs have been identified as predators on, and competitors with, several species of native ranid frogs (Kupferberg 1997. Ecology 78[6]:1736–1751; Twedt 1993. Comparative Ecology of *Rana aurora* and *Rana catesbeiana* Shaw at Freshwater Lagoon, Humboldt County, California, Unpubl. MS Thesis, Humboldt State University, 53 pp.). They have also been

observed to interfere with reproductive activity in *Rana aurora aurora* and *R. a. draytonii* (Storm 1953. Herpetologica 8:109; Twedt 1993, *op. cit.*; M. Jennings and M. Hayes, pers. comm.; G. Fellers, pers. comm.). In addition, bullfrogs might be vectors of disease when introduced outside their range (D. E. Green, pers. comm.). Over the past two years, we have observed two instances of bullfrog interference with reproduction in *Rana boylii* in geographically distant areas of the latter's range. Both of these events involved male *R. boylii* in amplexus with female *R. catesbeiana*. The first event occurred in Rancheria Creek, Mendocino County, California on 22 April 2000. Initially, there were two male *R. boylii* in amplexus with the same subadult *R. catesbeiana*. One of the male *R. boylii* separated when placed in an enamel pan for photographs. The second event occurred in the Middle Fork of the Yuba River, < 100 m upstream of the confluence of Oregon Creek, Yuba County, California on 31 May 2002. Based on surveys over the last six years, *R. boylii* and *R. catesbeiana* are sympatric in this area. Eggs and larvae of *R. boylii* have not been observed in these surveys, but *R. boylii* is known to breed in nearby tributary streams (e.g., lower section of Oregon Creek). In this event, an adult *R. boylii* was first observed in amplexus with a subadult *R. catesbeiana* in the open, in a small pool along the river margin (Fig. 1). The disturbance created by our attempt to photograph the event caused the amplexing pair to take cover under a large boulder. Within a few seconds, the frogs emerged separately from under the boulder. We do not know the extent of these interactions beyond the two observations described here. However, the implications for native ranid frogs and specifically for *Rana boylii* are disturbing and may constitute wasted reproductive effort on part of these native amphibians.

RANA OKALOOSAE (Florida Bog Frog): **PREDATION**. The Florida bog frog is one of the least studied frogs in North America, and predation of adults or tadpoles has not been reported. On 28 Aug 2002, a southern water snake (*Nerodia fasciata*) was observed actively foraging in the shallow (ca. 3 cm) headwaters of an unnamed branch of Live Oak Creek on Eglin Air Force Base in Okaloosa County, Florida. Within a 5-min period, the snake ate two *R. okaloosae* tadpoles, an unidentified salamander and attempted to capture a juvenile bog frog.

RANA SUBAQUAVOCALIS (Ramsey Canyon Leopard Frog). **DIET.** *Rana subaquavocalis* is the most recently described member of the *Rana pipiens* complex in the southwestern USA (Platz 1993. J. Herpetol. 27:154–162). Its range is limited to the Huachuca Mountains in southeastern Arizona, USA. Much natural history of this species remains unstudied. The diet of adult *R. subaquavocalis* has not been studied although is assumed to be similar to that of other members of the *R. pipiens* complex from the western USA (Sredl, *in press*. *In* M.J. Lannoo [ed.]. Status and Conservation of U.S. Amphibians Vol 2: Species Accounts. Univ. California Press, Berkeley.). Adult *R. subaquavocalis* often reach 90–120 mm SVL (Platz 1997. J. Herpetol. 31:552–557), which allows for sizable prey. The diet of other western leopard frogs is known to include a large variety of prey including terrestrial and aquatic invertebrates and vertebrates.

On 27 June 2002 at 1300 h a hummingbird was observed hovering ca. 150 mm above the water of a 13 x 8 m ornamental pond containing *R. subaquavocalis* at Beatty's Guest Ranch in Miller Canyon, Huachuca Mountains, Cochise County, Arizona. The hummingbird was either a rufous or an Allen's hummingbird, the two of which are often indistinguishable in the field (Robbins et al. 1983. Birds of North America: A Guide to Field Identification. Golden Press, New York. 360 pp.). An adult *R. subaquavocalis* successfully captured the hummingbird. The frog had its mouth partially open with none of the bird easily visible inside at 1322 h. We are unsure as to whether the frog was able to ingest and digest the bird completely, however, a bloated frog with its mouth closed was seen in the same location at ca. 1345 h. To our knowledge, this is the first documented observation of *R. subaquavocalis* successfully preying upon avian species and represents the only published data on diet.

BEATTY JR.**, Beatty's Guest Ranch, 2173 East Miller Canyon Road, Hereford, Arizona, 85615-9667, USA (e-mail: beattybb@theriver.com).

RANA SYLVATICA (Wood Frog). **BREEDING BEHAVIOR DURING DROUGHT**. The breeding behavior of *Rana sylvatica* in southern New England is well described. Typically, large aggregations of males congregate in seasonally flooded ponds during March and early April, where they float on the water's surface, and call when water temperatures are > 10.5°C. Thus, calling activity is greatest during mid-afternoon (Crouch and Paton 2002. J. Herpetol. 36:185–192). Egg deposition generally occurs in shallow water, with most egg masses attached to woody vegetation in communal deposition sites (Crouch and Paton 2000. Wildl. Soc. Bull. 28:895–901; Egan 2001. M.S. Thesis, Univ. Rhode Island). However, the effects of drought on courtship displays and egg deposition of *R. sylvatica* have not been documented. We report here on observations of aberrant breeding behavior during a drought in Rhode Island during 2002, when many breeding ponds were dry until late March.

On 16 March 2002, a group of 4 observers heard a wood frog chorus at 1230 h in a 0.6 ha pond basin (41°26'N, 71°39'W, Washington County, Rhode Island). Upon closer inspection, we found ca. 90 pairs of wood frogs in amplexus in full chorus calling from dry leaf litter in upland habitat, ca. 8 m from the edge of the pond basin. During this time, we observed at least three females depositing egg masses in dry leaf litter. It had rained 1 mm the previous evening, but there was no surface water or moist areas in the pond basin. Frogs were calling from within a closed-canopy forest dominated by red maple (*Acer rubrum*) and green briar (*Smilax rotundifolia*). Two observers revisited the same area on 17 March at 1030 h and found a communal deposition site with 56 egg masses within a 0.3 m radius area, and another 15 egg masses within 1 m of the communal deposition site. All egg masses were deposited on top of dry leaves. During an extensive survey of the entire pond basin on 17 March 2002, we found 8 egg masses deposited on dry ground and 7 dead, desiccated adults throughout the basin. The dead individuals lacked external signs of injury. The pond basin had no canopy cover and all dead animals were detected in open areas exposed to the sun. This pond remained dry until 26 March, with no further evidence of *R. sylvatica* egg deposition until 27 March. It rained 3.1 cm during the afternoon and evening of 26 March, which inundated the pond basin with 0.5 m of water. On 27 March, we found 379 egg masses in 4 communal depositions sites within the flooded pond basin. After 27 March, rains intensified, and many pond basins in the region that previously were dry became inundated and remained flooded until at least late June 2002.

From 17 March to 2 April, we documented 10 instances where *R. sylvatica* deposited egg masses within dry pond basins in Rhode Island and Massachusetts (Table 1). Observations at one pond in Arcadia Management Area, Rhode Island (41°35'N, 71°42'W) on 17 March were particularly unusual. The dry pond basin contained ca. 175 dead adult wood frogs, primarily pairs in amplexus. None of these dead animals exhibited external signs of trauma. In addition, there were at least 20 egg masses deposited on top of dry leaves and moss. A survey of this pond basin on 21 March detected 66 egg masses deposited on dry ground. This pond also had no canopy cover and all dead animals were found in exposed areas in the center of the basin. This pond contained a 2 x 2 m hand-dug pit located toward the center of the pond basin, with very steep sloping sides leading to the bottom of the pit. Water was < 30 cm deep in this pit, with 34 *R. sylvatica* egg masses and 10 dead adults. All other egg masses were on dry land and 165 dead, desiccated animals were found outside the pit.

We also documented frogs probably relocating to alternate breeding ponds in response to the drought when the alternate pond was < 50 m away. We monitored one pond (hereafter South Pond; 41°29'N, 71°37'W, Washington County, Rhode Island) with a drift fence array from 1997 to 2002 (except 1999). A heavily traveled paved road (State Route 138) was located 8 m NNE of South Pond. A second breeding pond (hereafter North Pond) was located 31 m

TABLE 1. Description of ponds in Rhode Island and Massachusetts where aberrant breeding behavior of *Rana sylvatica* was documented during a drought in 2002.

Date	Pond coordinates	Water depth (cm)	No. egg masses	Notes
17 March	41°35'N, 71°43'W	0	44	Pond dry up to 17 Mar, 44 egg masses detected in center of pond basin apparently deposited on dry ground
17 March	41°35'N, 71°42'W	0	20	20 egg masses deposited on dry ground, 175 dead, desiccated adults found in pond basin.
25 March	41°25'N, 71°37'W	0	54	Egg masses deposited on dry ground in deepest part of basin
25 March	41°24'N, 71°37'W	0	117	Egg masses deposited on dry ground in deepest part of basin
27 March	41°56'N, 71°41'W	10	240	100 egg masses deposited on dry ground, 140 egg masses deposited, 7 dead adults in basin
30 March	41°32'N, 71°35'W	15	227	22 egg masses deposited before basin filled on March 27th, remaining 205 were freshly deposited after latest rain
1 April	42°22'N, 72°18'W	0*	**	Adults in chorus and depositing eggs on moist ground, 627 m to nearest other breeding site
3 April	41°24'N, 71°33'W	0	65	Egg masses deposited on dry ground in deepest part of basin.
7 Apr	41°24'N, 71°32'W	0	65	Egg masses deposited on dry ground, 22 m from permanent pond

* Water table 3 cm below surface based on well.

** Present but not counted.

NNE of South Pond on the N side of Route 138. North Pond had a longer hydroperiod, typically drying 1–2 months later than South Pond. In most years, *R. sylvatica* emigrating from South Pond departed towards forested habitats to the ENE (1997: mean emigration direction 59.1°, SE = 11.6°, Rayleigh test of uniformity, $P < 0.01$, $N = 253$; circular statistics calculated with Oriana for Windows), or NW (1998: mean emigration direction 324.5°, SE = 1.9°, Rayleigh test of uniformity, $P < 0.01$, $N = 555$), or randomly when few animals immigrated to South Pond, (2001; Rayleigh test of uniformity, $P = 0.13$; $N = 17$). In 2002, South Pond did not contain surface water until 27 March, whereas North Pond had surface water on 1 March. We documented male *R. sylvatica* calling activity at North Pond from 9 March through at least 28 March. As in past years, adult *R. sylvatica* in 2001 immigrated to South Pond from all directions. Yet in contrast to previous years, adults moved to the NNE corner of pond basin, usually within 1–2 days of entering the array, and emigrated towards North Pond (2002: mean emigration direction = 21.6° SE = 4.5, Rayleigh test of uniformity, $P < 0.01$, $N = 166$). North Pond had at least 220 wood frog egg masses on 21 March 2002, whereas there were no egg masses in the dry pond basin of South Pond on 21 March 2002. It was not until 27 March 2002 that 18 new egg masses were detected in South Pond, when 5 cm of water was present in the deepest part of the pond basin.

We also observed the probable relocation of breeding adults to an alternate breeding pond at a pair of ponds in Arcadia Management Area, 41°35'N, 71°44'W, Washington County, Rhode Island. These two ponds are 15 m apart; one is a small pond (0.02 ha) with a relatively short hydroperiod (typically drying in July), whereas the larger, deeper pond (0.04 ha) has a longer hydroperiod (usually drying in November or permanent in some years). We counted egg masses in both ponds from 1996 to 2001 (large pond: 6-yr mean = 138.7 (SE = 36.2), range 18–245 egg masses annually; small pond: mean = 164.3 (SE = 20.1), range = 65–225; CJR, unpubl. data). In 2002, the small pond was completely dry during March, whereas the large pond had 15 cm of water on 10 March. No egg masses or dead adult *R. sylvatica* were detected in the small pond in 2002, whereas we heard adults chorusing and found 50 egg masses in the large pond on 13 March and 160 egg masses on 17 March. This suggests that adults may have relocated their deposition site from the small pond basin to large basin in 2002, we suspect in response to water availability and chorusing frogs.

The drought conditions experienced in Rhode Island were extreme during March 2002; in over 20 years of fieldwork in Rhode Island, CJR had never seen pond basins at sites used by breeding *R. sylvatica* dry during this time of year. One explanation for the aberrant behavior we documented is that adults still migrated to ponds in early to mid-March, although most ponds had no surface water. At some isolated, dry pond basins (defined here as ponds > 200 m from any other pond basin with water), males initiated choruses despite the fact that no water was present, which attracted females to ponds. Males initiated amplexus with females in these dry situations and we hypothesize that females then had to deposit eggs because males would not dismount from females until eggs were deposited. In pond basins with no canopy closure, *R. sylvatica* apparently initiated courtship behavior in areas where they were exposed to overheating. In situations where alternate breeding sites with standing water were available < 100 m away and supported male chorus activity, *R. sylvatica* apparently relocated to alternate breeding ponds.

In Rhode Island, egg deposition chronology of spotted salamanders (*Ambystoma maculatum*) is similar to *R. sylvatica* (Paton and Crouch 2002. Cons. Biol. 18:194–204). However, no *A. maculatum* egg masses were observed in any dry ponds we surveyed. *A. maculatum* must have either delayed egg deposition until the ponds filled or may have skipped breeding entirely. Erratic breeding patterns in *A. maculatum* have been previously documented, with about 90% of adults breeding annually in a Rhode Island population (Whitford and Vinegar 1966. Copeia 1966:515–519). Because *A. maculatum* is a longed-lived species (up to 38 years; Flageole and Leclair 1992. Can. J. Zool. 70:740–749), and generally exhibit relatively high adult survivorship, they can afford to pass over a reproductive opportunity that has a high potential of failure to conserve that energy for survival to the next breeding season when conditions may be better. In comparison, male *R. sylvatica* often have only one opportunity to breed in their lifetime. Approximately 84% bred once, 14% bred twice, and only 2% bred three times in a Maryland population (Berven 1990. Ecology 71:1599–1608). A wood frog's overall fitness may depend on one breeding event and therefore this species cannot afford to postpone breeding to a time when conditions are more favorable, even if egg masses are deposited on dry land as we observed.

Based on our observations, the aberrant breeding behavior of *R. sylvatica* we documented during Spring 2002 was a widespread phenomenon throughout drought-stricken areas of southern New England. Past research has documented the importance of pond hydroperiod to survival of larval amphibians (e.g., Paton and Crouch 2002, *op. cit.*). The 2002 drought stresses the potential impact that hydroperiod can have on adult survival and reproductive success. In addition, these observations support the importance of maintaining multiple breeding ponds within close proximity with varying hydroperiods to ensure population viability.

RANA TEMPORARIA (Common Frog) and ***BUFO FOWLERI*** (Fowler's Toad) **TADPOLES. PROTOZOAN INFESTATION**. Sessile ciliate protozoans (Peritrichia) colonize exposed parts of aquatic organisms including amphibian larvae (e.g., *Scyphidia*, *Opercularia* and *Vorticella* in buccal cavities of tadpoles of *Bufo bufo* and *Rana* kl. *esculenta*; Viertel 1979. Salamandra 15:60–62). They are not direct parasites but in high densities may hinder host movement and feeding efficiency. We report two such occurrences with no information on possible effects on the tadpoles or the environmental conditions that may have promoted the infestations. In light of amphibian declines and malformities, these infestations, the species and stages of the hosts and protozoans involved, and the ecological situations in which they occur should be noted so that possible correlations can be detected.

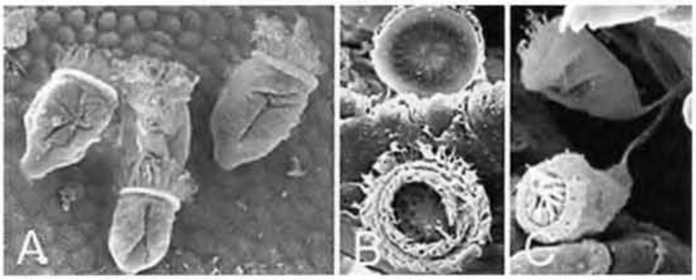

FIG. 1. Peritrichian protozoans attached (A) to the roof of the buccal cavity of *Rana temporaria* tadpoles and (B) at the base of the jaw sheath serrations, and C) between the tooth rows of *Bufo fowleri*.

Rana temporaria tadpoles from the Pyrenean Mountains (Circo de Piedrafita, Aragon, Spain, July 1999) had dense aggregates of peritrichians (Fig. 1A; up to 150–200 specimens on the buccal roof of one tadpole) in the buccal cavities. Tadpoles from ponds C and J out of 11 (Vences et al. 2002. J. Zool. Lond. 257:155–167; single specimens per pond examined with SEM) were infested. These ponds had low tadpole densities (4–11 specimens/m^3) and differed in size (70 vs. 1065 m^2 surface area) and water depth. Tadpoles were in Gosner stages 36–40 (Gosner 1960. Herpetologica 16:183–190). The peritrichians were tentatively identified as *Scyphidia amphibiarum* (Nenninger 1948. Zool. Jahrb. Syst. 77:169–266; described from external skin of tadpoles) based on their short, stout shape, rather distinct peristomal bulge, and many distinct small horizontal furrows on the pellicula.

Eight of 57 tadpoles (Gosner stages 33–36) of *Bufo fowleri* (Bradley Creek, Rutherford County, Tennessee, Spring 2000 and 2001, Gosner stages 25–37; examined with SEM) had ciliates attached along the inner base of the jaw sheaths serrations (Fig. 1B), between tooth rows (Fig. 1C), and on the skin adjacent to the oral disc. Internal examinations were not made, and there were no obvious effects of the infestations on the tadpoles. These peritrichians clearly belonged to a different taxon than those above based on the less distinct peristomal bulge and the long and narrow shape, although a reliable identification was not possible.

RANA VAILLANTI (Web-footed Frog). **DIET**. Although geographically widespread and locally abundant, few details are known about the diet of *Rana vaillanti*. Arthropods, fishes, frogs, birds, and possibly small mammals comprise the diet (Noble 1918. Bull. Amer. Mus. Nat. Hist. 38:311–347; Ramirez et al. 1998. J. Herpetol. 32:338–344; Savage 2002. The Amphibians and Reptiles of Costa Rica. Univ. Chicago Press. 934 pp.). Although frogs are known to occur in its diet, only conspecifics have been identified as prey.

On 7 Sept 2002 at 1820 h an act of predation was observed 3 km N of Tirimbina Rainforest Reserve in Sarapiqui, Heredia, Costa Rica. A *Rana vaillanti* (mass 93.0 g) was sitting at the edge of a small pond in late second growth and cacao with the hind legs of an *Agalychnis callidryas* (mass 5.0 g) protruding from its mouth. The *R. vaillanti* was captured and the *A. callidryas* removed. Although dead, the *A. callidryas* was virtually unmarked by the capture and subsequent partial ingestion. The prey/predator mass ratio was 0.054. Many *R. vaillanti* were active in and around the pond. Several *A. callidryas* were calling from vegetation at the pond's edge, and amplexing pairs were observed. Presumably the *A. callidryas* was at or very near ground level when captured by the *R. vaillanti*. This is the first record of any frog other than a conspecific in the diet of *R. vaillanti*.

SCINAX ALTERA (NCN). **PREDATION**. Although tadpoles and metamorphosing anurans often are prey for a variety of invertebrates (Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill, New York. 670 pp.; Hinshaw and Sullivan 1990. J. Herpetol. 24:196–197), there are few reports of predation on adults (Bastos et al. 1994. Herpetol. Rev. 25:118; Bastos and Haddad 1997. Amph.-Rept. 18:295–298; Hinshaw and Sullivan, *op. cit.*). Most spiders in the genus *Ancylometes* are recognized predators of small vertebrates including frogs, tadpoles, and fishes (Bernarde et al. 1999. Biociências 7[1]:199–203; Brescovit 2000. Insect Syst. Evol. 31[3]:323–360). Herein we report predation on adult *Scinax altera* (SVL = 27.3 mm) by a female *Ancylometes rufus* (23 mm cephalothorax and abdomen length, MNRJ 3489, Museu Nacional, Rio de Janeiro, Brazil) in a swamp at Reserva Biológica de Duas Bocas (20°16'51"S, 40°28'37"W), a biological conservation area located in the Municipality of Cariacica, State of Espírito Santo, Brazil. On 23 Dec 2001 at 0100 h (air temp. 23.5°C, water temp. 29°C) the spider was perched on the leaves of the aquatic plant *Typha dominguensis* about 30 cm above the water surface sup-

FIG. 1. Predation of an adult *Scinax altera* (SVL = 27.3 mm) by a female *Ancylometes rufus* (23 mm cephalothorax + abdomen length).

porting the hylid with pedipalps and first pair of legs (Fig. 1). The chelicerae penetrated the lateral region of the frog.

We thank Renner L.C. Baptista, Museu Nacional, Rio de Janeiro, for identification of the spider, IDAF – ES for permission to conduct field work and for logistic support, and CAPES for financial support (G.M. Prado). J. P. Pombal Jr. and P. Passos commented on a draft.

TESTUDINES

CHELYDRA SERPENTINA (Common Snapping Turtle). **REPRODUCTION.** On the morning of 7 June 2001, we observed a 2.9 kg female *Chelydra serpentina* digging a nest at the edge of a gravel road in Utica Marsh, an urban wetland next to the Mohawk River and lying partially within the city limits of Utica, New York, USA. The nest site was 53 m from the water on a direct line and within a ca. 30 x 60 m cleared area with a gravel road running along one margin. On closer inspection of the nesting activity, we found several damaged *C. serpentina* eggs from a prior nest in the soil being dug up by the female. As she continued digging, additional eggs surfaced. Palpation of the pelvic region of the laying female indicated that she had a full load of shelled eggs ready for oviposition. We left the animal undisturbed for an hour, and upon return, found the female covering the nest. We found numerous additional broken eggs around the nest site. Palpation indicated that no eggs remained in her body cavity. Twenty-three eggs were recovered from this nest and collected for hatching in the lab. Three undamaged eggs were salvaged from the previous nest of an estimated 15–20 eggs total.

To our knowledge, this represents a rare instance of *C. serpentina* using a previously excavated nest for her own, thus destroying the eggs of the first female. Anecdotal evidence provided by others suggests that this phenomenon has been observed in several species, including snapping turtles, wood turtles, and sea turtles. One published study of nesting in *Malaclemys terrapin* reported that females would occasionally dig up other nests in high density nesting areas, but such incidents represented less than 2% of total nesting events (Burger 1977. Am. Midl. Nat. 97:444–464). We have been unable to find published reports of this type of nest destruction by *C. serpentina*, and such activity was not documented by Congdon et al. (1987. Herpetologica 43:39–54) in their thorough study of nesting ecology of *C. serpentina*.

Although *C. serpentina* nest predation by other species is well established, it remains puzzling as to what mechanism other than chance led to this observed nest destruction by *C. serpentina* in a low-density nesting area containing only six nest sites within this 1800 m^2 nesting area. Difference in soil structure does not appear to be a factor nor does relative openness of each nest site in the area. One could speculate whether olfactory cues may have contributed to selecting the first nest as the site to excavate.

CHELYDRA SERPENTINA (Common Snapping Turtle). **SITE FIDELITY AND GROWTH.** On 9 July 1996 two *Chelydra serpentina* were individually marked with Trovan™ pit tags (InfoPet™, Burnsville, MN) and released in Salado Creek, Independence Co., Arkansas, USA (T12N, R5W, Sec. 7). On 2 July 2001, we retrieved one of the pit-tagged individuals, a male *C. serpentina* from a fish-baited, 1.2 m double-throated hoop net at the exact same trap site located ca. 1.1 km from the confluence of Salado Creek and the White River, 8.0 km SE of the White River Access, Batesville, Arkansas. In 1996 the turtle's measurements were as follows: mass (MA) = 2.27 kg, curved carapace length (CCL) = 230 mm, pre-anal tail length (PRT) = 95 mm, and post-anal tail length (POT) = 149 mm. Standard carapace length (SCL) was not recorded on the initial capture. In 2001, the measurements were as follows: MA = 2.81 kg, CCL = 243 mm, PRT = 96 mm, POT = 131 mm, and SCL = 237 mm.

Few studies have tracked growth rates in adult *C. serpentina* over extended periods (Brown et al. 1994. J. Herpetol. 28:405–410; Galbraith et al. 1989. Copeia 1989:896–904), although growth is typically considered predictable using growth ring proportional analysis of growth ring–standard carapace length associations (Sergeev 1937. Zool. Zh. 16:723–235) this turtle's age could not be obtained from plastral scutes because only a few ridges were still present.

Galbraith et al. (*op. cit.*) showed that SCL of female *C. serpentina* from Ontario, Canada increased as follows: 24% between the age of 10 and 15 years old, 10% growth between 15 and 20 years, and 4% from their 20th to 25th year. However, in an Iowa study (Christiansen and Burken 1979. Herpetologica 35:261–266) SCL increased 3.7% between the 11th and 16th year. While we cannot document the increase in SCL, the growth in PRT was 2%, while increase in CCL was near 5%, and mass increased 19%. If we assume that growth in PRT is proportional to that of SCL then SCL in 1996 was about 234 mm based on a 2% PRT growth rate. If it is proportional to CCL then the 1996 SCL was closer to 224 mm based on a 5% growth rate. Galbraith et al. (*op. cit.*) suggested that females in northern populations reach reproductive maturity at a larger size and greater age than those from southern populations. Based on this model, our Arkansas specimen is about the same size as expected for a female 15 year-old Ontario *C. serpentina* (236 ± 2.37 mm, N = 19) or a female 11 to 12 year-old Iowa specimen (233.3 ± 2.36 mm). This would suggest that this male specimen was probably no older than 11 years old and likely substantially younger.

A large population of alligator snapping turtles (*Macroclemys temminickii*) is known from Salado Creek (Trauth et al. 1998. Chel. Conserv. Biol. 3:64–70). The reduction in POT can be attributed to an apparent tail loss, possibly through interspecific or intraspecific aggression between Chelydridae in this stream. The tail appeared to have healed and then regrew as it was tapered fairly normally. Tail loss in *M. temminckii* is discussed in McCallum and Trauth (2000. J. Arkansas Acad. Sci. 54:150–152).

Our observation also suggests that *C. serpentina* displays strong site fidelity in their home range over extended periods. This is an important factor for professionals interested in this species' habitat preservation, management and population relocation. If inherently strong site fidelity is characteristic of this species, then major modifications to stream channels, draining of water bodies, and other such anthropogenic disturbances might pose a threat to these animals especially if they begin experiencing population declines in the future. Under such circumstances it would be essential to preserve the physical nature of localized habitats to reduce stress on the studied populations.

GEOCHELONE RADIATA (Radiated Tortoise). **NOCTURNAL ACTIVITY.** Radiated tortoises (*Geochelone radiata*) are normally active during the day between 0700–1200 h and again between 1400–1700 h (pers. obs.). On the evening of 29 March 2000 at 2054 h two adult tortoises were found actively walking around in the dark on a rocky path near the village of Befeha (Cap Sainte Marie), Madagascar. This was the only incidence of nocturnal activity seen during the 1998–2000 study.

Several North American emydids including *Emydoidea blandingii, Terrapene carolina, Chrysemys picta, Chelydra serpentina,* and the four species of *Clemmys* are known to be active at night when searching for or excavating nests (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 578 pp.). Night-time nesting is also reported for two tortoise species—*Kinixys spekii* (Hailey and Coulson 1997. Brit. Herpetol. Soc. Bull. 58:11–18) and *Testudo hermanni* (Swingland and Stubbs 1985. J. Zool., Lond. 205:595–610).

However, here the microhabitat was inappropriate for nesting because of the presence of large rocks. All nests observed in Madagascar were laid in sandy-soil (N = 24) in the mornings (0700–1000 h). It is more likely that the tortoises were active in response to rain. Adest et al. (1988. Herpetol. Rev. 19:75–76) reports nocturnal activity in Bolson tortoises *(Gopherus flavomarginatus)* because of elevated ambient burrow and/or soil temperatures, and in response to night rains. The 2000 field season had been very dry. In February of 1999, Cap Sainte Marie had 792 mm of rain compared to 1.95 mm in February 2000. At 1930 h on 29 March there had been 0.8 mm of rainfall. Tortoises, on several other occasions, were seen drinking water that accumulated in the crevices of flat rocks *(ranovato)* after rains.

I thank Conservation International, Wildlife Conservation Society, FOCAL Ind., George Mason University, and Chelonian Research Foundation for their financial support of this project. Thanks to FANAMBY (Antananarivo, Madagascar) for providing a research vehicle and a driver.

GLYPTEMYS (= CLEMMYS) MUHLENBERGII (Bog Turtle). **ABNORMAL COLORATION**. On 17 June 2002, a male *Glyptemys muhlenbergii* with white neck patches and white skin around the tympanum was found (by MK) in Sussex County, New Jersey. The turtle was previously found and marked (by JT) on 30 May 2000. Typical coloration of the neck patch and skin around the tympanum in Bog Turtles ranges from yellow to orange or red (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington). Abnormally-colored Bog Turtles with piebald or albino characteristics have been rarely observed (D. Herman, pers. comm.; S. Smith, pers. comm.).

The Bog Turtle noted here was approximately 10 years old when photographed, and appeared healthy. The neck patches and skin around the tympanum were white to the edges, with no other apparent color. Iron staining was present on the white patches, but was easily removed. The eyes were dark brown and the turtle's coloration appeared normal in all other respects.

The turtle was found in a calcareous tussock sedge (*Carex stricta*) and cattail (*Typha latifolia*) meadow and had moved more than 160 m between captures. It has been suggested that diet may influence skin color in this species (D. Herman, M. Klemens, and S. Smith, pers. comm.). However, 42 Bog Turtles have been marked over the past six years within this wetland complex and all had orange or red neck patches.

We thank Dennis Herman, Michael Klemens, Jim Warner, and Scott Smith for graciously sharing their knowledge about Bog Turtles, and Laura Newgard and Lisa Arroyo for field assistance. We also thank the New Jersey Division of Fish and Wildlife for Bog Turtle data and EcolSciences, Inc. for time and financial support.

GOPHERUS POLYPHEMUS (Gopher Tortoise). **NESTING.** Gopher tortoises are widely reported to nest in burrow aprons, with active burrows being more commonly used than inactive or abandoned burrows (Demuth 2001. Can. J. Zool. 79:1609–1620; Smith 1995. Bull. Florida Mus. Nat. Hist. 3, Pt I[4]:97–126). It is also believed that gopher tortoises lay only one clutch of 3–10 eggs per year (Iverson 1980. Am. Midl. Nat. 103:353–359; Smith 1995, *op cit.*). Here we report two clutches of average size occurring in the same burrow apron.

On 18 June 2002 at Merritt Island National Wildlife Refuge, Brevard County, Florida (USA), active burrow aprons were being excavated in overgrown scrub edge habitat to locate gopher tortoise nests. Two nests were found within the same burrow apron while a resident tortoise was inside the burrow. The first nest contained 4 eggs and was located 5 cm from the burrow opening, 3 cm below the surface. The second clutch contained 5 eggs and was located 22 cm from the opening, 5 cm below the surface.

Both clutches were directly in front of the burrow entrance in line with each other and the entrance. Before beginning excavation of the burrow apron we noted three small depressions located around the periphery of the burrow (~1 m from the entrance) that appeared to be failed attempts at nest excavation by a tortoise. The sex of the resident tortoise was not determined.

As Gopher Tortoises have not previously been reported to produce more than one discrete clutch per year, it is possible that these clutches represent the efforts of two tortoises using the same burrow apron. Alternately, this might represent the first known occurrence of a Gopher Tortoise producing more than one clutch of eggs in a season.

We thank the U.S. Fish and Wildlife Service at Merritt Island NWR and the National Park Service at Canaveral National Seashore for support.

Submitted by **DAVID A. PIKE**, Towson University, Department of Biological Sciences, 8000 York Road, Towson, Maryland 21252, USA (e-mail: dpike1@towson.edu) and **LAUREL PIERPONT**, National Park Service, Canaveral National Seashore, 308 Julia Street, Titusville, Florida 32796, USA.

GOPHERUS POLYPHEMUS (Gopher Tortoise). **MORTALITY.** On 7 June 1999, a Gopher Tortoise hatchling was radio-located that had been killed by a prescribed fire on the DeSoto National Forest, Mississippi, USA. The hatchling was found on the surface ca. 5.5 m from a burrow that it had constructed and inhabited since the previous fall. Prior to the fire, the last location was on 3 June 1999, and the hatchling was found alive and in the burrow. On 5 June 1999, the U.S. Forest Service ignited a prescribed fire. The habitat consisted of a longleaf pine (*Pinus palustris*) overstory and a bluestem (*Andropogon* spp.) dominated understory, and is burned on a 3–4 year rotation.

Gopher Tortoises inhabit upland ecosystems of the southeastern coastal plain that are fire-dependent (Means and Campbell 1981. *In* Wood [ed.], Prescribed Fire and Wildlife in Southern Forests, pp. 89–97. Belle W. Baruch Forest Science Institute of Clemson University, Georgetown, South Carolina). Historically, many of these fires were ignited by lightning strikes (Komerek 1964. Tall Timbers Fire Ecology Conference Proceedings 3:139–183). Currently land managers frequently use prescribed fire to mimic the natural fire regime. Fire-induced mortality of herpetofauna in this ecosystem is thought to be minimal as many species have behavioral adaptations to escape fire. The Gopher Tortoise is a fossorial species that excavates and inhabits a burrow, which provides protection from temperature extremes as well as fire. This is apparently the first recorded mortality of a Gopher Tortoise by prescribed fire. The positive impacts of habitat improvement undoubtedly outweigh rare mortalities.

GRAPTEMYS GEOGRAPHICA (Northern Map Turtle). **NEST OVERWINTERING.** From 14–21 May 1994, at least 24 hatchling *G. geographica* were recovered crossing West (River) Road, near "E area," Savanna Army Depot, Jo Daviess County, Illinois and released in Crooked Slough. No measurements were taken, but none of the hatchlings had plastral growth annuli, nor did they have external evidence of yolk sacs or unhealed umbilical scars. Adult females were recovered during the same period migrating from Crooked Slough and the Mississippi River proper to the extensive nesting sites in the sand prairies east of West Road. No migrating females were observed prior to 14 May, and no hatchlings were observed after 21 May. The nesting period occurs in the area from May to July and hatchling emergence typically occurs from August through September; however, hatchlings may overwinter in the nest in parts of their range (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington, D.C.). These observations suggest that hatchling Northern Map Turtles from extreme northern Illinois may over winter in the nest, or alternatively at some location near the nest site.

I thank Edward O. Moll and Eastern Illinois University for support while conducting this study, and Stanley E. Trauth for comments on the manuscript.

KINOSTERNON SONORIENSE (Sonoran Mud Turtle) and ***BUFO PUNCTATUS*** (Red-spotted Toad). **PREDATOR-PREY.** On 3 July 1999, at 0920 h, we observed an adult male *Kinosternon sonoriense* consuming an adult male *Bufo punctatus*. At the time that our approach disturbed the turtle, the contents of the toad's ventral cavity had been consumed; left remaining were the head, vertebral column, portions of the pelvic and pectoral girdles, and the dorsal dermis, including all portions covered with tubercles. The remains of a second *B. punctatus* in similar condition were discovered on 16 July 1999.

Both observations were made in small pools in the Peloncillo Mountains, Hidalgo Co., New Mexico, USA. Rains preceded the discovery of both *B. punctatus* carcasses by 18 h or less (1.2 cm and 0.3 cm, respectively), and toads were heard calling on both days. Three pairs of *B. punctatus* were observed in amplexus on 3 July, the first day we observed anuran breeding in the study area that year.

Based on the remains of the two toads (University of Central Oklahoma Collection of Vertebrates, UCO 0720 and 0723) it appears that *K. sonoriense* readily preys on adult *B. punctatus*, but actively avoid consuming their potentially poisonous tubercles. Consumption of *Bufo* has not been previously reported, though the diet of Arizona populations of *K. sonoriense* has been described from stomach contents (Hulse 1974. J. Herpetol. 8:195–199). Our observations add to the list of dietary items known for this species, and represent the second anuran prey reported. We assume that our observations represent cases of predation; however, it is possible that the toads died of unrelated causes, and were subsequently scavenged by *K. sonoriense*.

We thank the College of Graduate Studies & Research at the University of Central Oklahoma for financial support. This study was conducted under New Mexico Department of Game and Fish

PSEUDEMYS RUBRIVENTRIS (Red-bellied Cooter). **CO-JOINED TWINS**. Axial bifurcation, including bicephalism and bifurcated tails, is a well known malformation in reptiles (Cunningham 1937. Axial Bifurcation in Serpents, Duke Univ. Press, Durham, North Carolina, 117 pp.; Bechtel 1995. Reptile and Amphibian Variants, Krieger Publ. Co., Malabar, Florida, 206 pp.). A hatchling *Pseudemys nelsoni* reported by Bellairs (1981. *In* J. E. Cooper and O. F. Jackson [eds.], Diseases of Reptiles, Vol. 2, pp. 469–485. Academic Press, London) had a partially duplicated carapace and plastron, two heads and anterior limbs, two hearts, respiratory systems, livers, and stomachs, and a single urogenital system, intestine, and cloaca. Here I note an additional instance of co-joined twins in *Pseudemys,* the first reported for *Pseudemys rubriventris*.

On 5 September 2000, Robert Carter found a co-joined twin *Pseudemys rubriventris* adjacent to Bosher's Mill Pond, 0.5 km E Manquin, King William County, Virginia, USA (Fig. 1). He observed normal hatchlings emerging rapidly from the nest and upon inspection found the twins in the bottom of the nest cavity, apparently unable to emerge on their own. The twins had the following measurements: maximum carapace length (CL) = 34.1 mm, maximum plastron length (PL) = 30.9 mm, carapace width = 33.8 mm, and shell height (SH) = 16.6 mm. Two normal siblings measured 34.5 and 34.9 mm CL, 31.7 and 31.8 mm PL, and 17.3 and 17.6 mm SH, respectively. A radiograph revealed two pectoral girdles, each with two pairs of legs and a neck and head, two separate vertebral columns, and one pelvic girdle with a single pair of rear legs. The vertebral columns joined at the sacrum. The nest was adjacent to a parking lot of a power line relay station. The carapace, plastron, head, and limbs were normal in coloration and pattern (Mitchell 1994. The Reptiles of Virginia, Smithsonian Inst. Press, Washington, DC, 352 pp.). In captivity, the left half dominated the right half in strength and direction of movement.

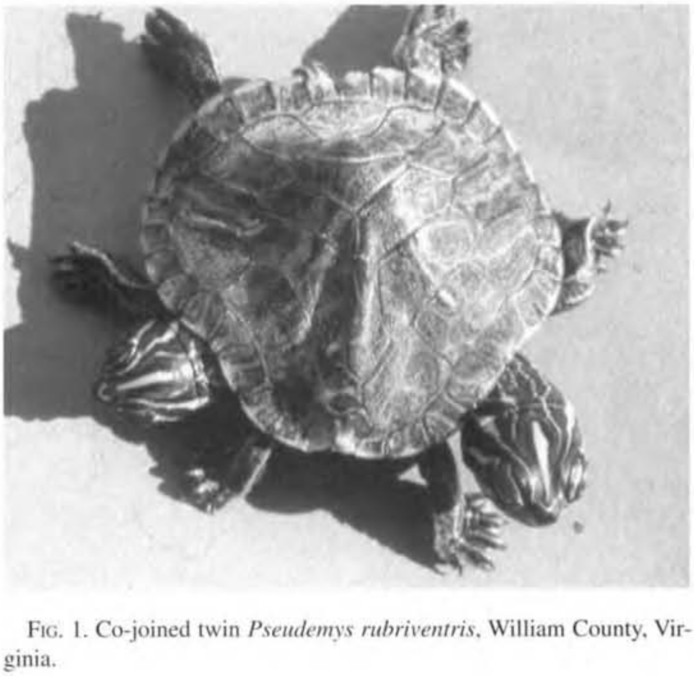

FIG. 1. Co-joined twin *Pseudemys rubriventris*, William County, Virginia.

I thank Robert Carter for allowing me to examine the twins, Deborah Grissom for taking the radiograph, and Elizabeth Pezzullo and Dale Brittle for other forms of assistance.

TRACHEMYS SCRIPTA ELEGANS (Red-eared slider). **MAXIMUM SIZE**. The maximum straight-line carapace length (CL) reported for *Trachemys scripta elegans* is 28.9 cm (Conant and Collins. 1998. A Field Guide to Reptiles and Amphibians: Eastern and Central North America. Houghton Mifflin Co, Boston. 616 pp.). On 25 September 2001 we found an intact *T. s. elegans* shell with a CL of 29.8 cm (CUSC 2101) on a bluff above Wards Creek (30°25.9'N; 91°07.8'W), ca. 1 km downstream from the bridge at College Dr., Baton Rouge, East Baton Rouge Parish, Louisiana, USA. There is extensive pitting of the plastron bone, and both carapace and plastral annuli are heavily eroded, thus precluding a reliable count. The turtle was probably killed by a raccoon (*Procyon lotor*) several months earlier while nesting. Other straight-line measurements are: plastron length = 25.9 cm; maximum shell depth = 13.2 cm; maximum carapace width = 21.9 cm. This specimen is deposited in the Campbell Museum, Clemson University, Clemson, South Carolina, USA.

RAINWATER**, The Institute of Environmental and Human Health, Department of Environmental Toxicology, Texas Tech University Box 41163, Lubbock, Texas 79409-1163, USA.

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider). **DIET.** *Trachemys scripta elegans* is an opportunistic omnivore known to consume a wide variety of plants and animals (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 578 pp.). Herein is the first report of *T. s. elegans* feeding on fruit of the pond apple tree (*Annona glabra*).

On the morning of 14 September 2002 at 0745 h, we observed two *T. s. elegans* feeding on *A. glabra* fruits that had fallen into the C-11 canal in Davie, Broward County, Florida, USA (26°03'56"N, 80°14'29"W). Two days later (16 September 2002), we captured an adult female *T. s. elegans* (carapace length 23.3 cm, plastron length 20.2 cm, mass 2150 g) in a turtle hoop trap baited with canned sardines. The trap was ca. 50 m from the initial observation of *T. s. elegans* feeding on *A. glabra* fruit. The captured turtle was brought back to the lab and maintained in captivity. On 17 September 2002, the turtle defecated and 11 *A. glabra* seeds were observed in its feces.

T. s. elegans is a non-indigenous yet abundant turtle in the freshwater canals of Broward County, Florida (G. Johnston, unpubl. data). However, very little is known about its impact on the native

flora and fauna of this region. Our observations suggest that *T. s. elegans* may play an important role in dispersing seeds of the native *A. glabra*.

CROCODYLIA

CAIMAN LATIROSTRIS (Broad-snouted Caiman). **BEHAVIOR**. Field studies providing information on parental behavior in *C. latirostris* have focused on nesting and nest protection (Verdade et al. 1992. *In* Proc.11th Work Meet. Croc. Spec. Group. IUCN - Switzerland.). Data addressing parental care and other adult-juvenile behaviors are especially scarce. Captive observations exist, but these have the limitation that the captive environment may interfere with the expression of selected behaviors. Thus, we report here on adult-hatchling interactions that may represent antipredator behavior among wild *C. latirostris* from southeastern Brazil.

Between 18 August and 4 September 1998, we conducted a census and field observations on a small relict group of *C. latirostris* living in Parque Estadual Intervales (Estado de São Paulo), SE Brazil. This group consisted of 2 adults (120–150 cm total length, TL), two subadults (80–100 cm TL) and 16 hatchlings (25–30 cm TL). Observations were made on a small (0.04 ha) lagoon at 315 m elevation (24°23'30"S; 48°29'50"W) created by damming a 1.5-m wide stream flowing from the Serra de Paranapiacaba. Vegetation around the lagoon consisted of herbaceous plants, native bamboo (*Merostachys* sp., Poaceae) and secondary forests (Guix et al. 2002. *In* Mateos et al. [eds.], Censuses of Vertebrates in a Brazilian Atlantic Rainforest Area: The Paranapiacaba Fragment, pp. 141–147. Centre de Recursos de Biodiversitat Animal, Universitat de Barcelona, Barcelona).

On 25 August around 1130 h, we encountered 8 hatchlings on the lagoon margin. Five were in low vegetation just 10–35 cm above the lagoon edge on logs, another 3 were in the water. When one observer approached this hatchling group to within 1 m, the hatchling closest to the observer began to vocalize. The hatchlings immediately began to vocalize, some jumped into the water and some remained on the lagoon margin. Simultaneously, an adult (> 120 cm) slipped off the lagoon margin, and swam toward the center of the lagoon where it began vocalizing. The remaining hatchlings jumped into the water while vocalizing, and then started swimming towards the adult. During this time, the hatchling that had initiated vocalization remained in the water 0.5 m in front of the observer. While most hatchlings fled toward the adult, we caught this hatchling, whereupon it began to vocalize louder. The adult then put its head out of the water at about a 45° angle with its mouth slightly open and vocalized very loudly for 3–5 seconds. After it stopped and put its head down, the hatchling we had in hand also stopped vocalizing.

On 1 September at 2130 h, upon approaching the lagoon margin from a distance of 3 m, we heard an adult *C. latirostris* vocalize. When we reached the lagoon we saw 5 hatchlings on the edge ca. 2 m away. Upon our appearance, one immediately made a plaintive vocalization, after which we saw 15 hatchlings flee in a waterward direction, diving and swimming towards the center of the lagoon. Low vegetation had concealed 10 hatchlings that were only noticed as they fled.

On 2 September at 1000 h, as we got to within 4 m of the lagoon, we heard an adult vocalize, but no hatchlings were seen; none may have been present. On 4 other occasions on different nights, when a hatchling was caught by an observer, it vocalized. Although we did not hear adults vocalize in these cases, they always approached observers, getting as close as 4 m in a slow and silent manner. After approach, adults remained immobile floating at the water surface with their heads out, slightly inclined.

Adults never tried to attack or keep us away from hatchlings; adults approaching observers handling hatchlings seemed more intimidating than agonistic. Hatchlings did not always vocalize when captured, nor did adults always necessarily respond when captured hatchlings vocalized. Of 16 observations in which we handled hatchlings, they were silent in 2 (13%) of them.

Many potential predators of hatchlings are potential prey for adult *C. latirostris*. In part because the relationship between adults and hatchlings was unknown (potentially parental or not), hatchling vocalizations and the approach behavior of adults may have alternate interpretations. These alternatives, which may not be mutually exclusive, include the protection of hatchlings from potential predators (see Steel 1989. Crocodiles. Christopher Helm, London. 198 pp.) through intimidation or agonistic behavior (when a non parental adult or subadult conspecific approaches hatchlings or at nest) and facilitation of the location of prey when hatchlings vocalize in response to the approach of a potential predator.

We thank Antonio Tufo, Kátia Pisciotta, Francesca B. L. Palmeira Eleonore Setz, Paulo R. Manzani, Luciano M. Verdade. and Walter Barrela and the guard staff of the P. E. Intervales. Marc P. Hayes provided helpful comments on various versions of the manuscript. The Fundaçao Florestal provided logistic support to conduct research in the Intervales Park.

LACERTILIA

AMPHISBAENA ALBA (White-bellied Worm Lizard). **REPRODUCTION**. Scattered reports of amphisbaenian eggs found in nature (Goeldi 1897. Zool. Jahrb. [Syst.] 10:640–676; Jared et al. 1997. Herpetol. Rev. 28:44–45) or in the oviducts of gravid females exist (Barros-Filho and Valverde 1996. Sitientibus 14:57–58), but amphisbaenian reproduction remains very poorly known (cf. Gans 1962. Amer. Mus. Novit. 2105:1–31). As far as known, the eggs of *Amphisbaena alba* are laid in ant nests (Riley et al. 1985. Herpetol. Rev. 16:38–43; Azevedo-Ramos and Moutinho 1994. Entomol. News 105:183–184), but egg-laying behavior is undescribed. Here, we provide the first data on oviposition behavior in *A. alba* based on a female collected in southeastern Brazil.

At 0700 h on 5 September 1997, during a faunal rescue for Hy-

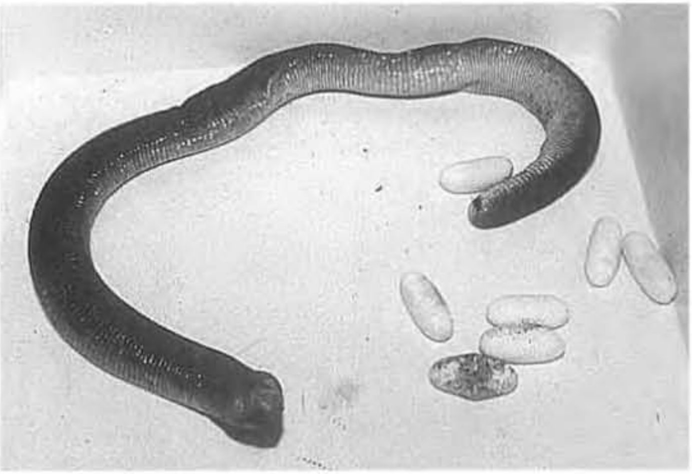

FIG. 1. Adult (ca. 55 cm total length) *Amphisbaena alba* during oviposition with seven of her recently laid eggs. One of the two eggs first deposited is darkened from fungi.

droelectric Usine Miranda in Indianópolis, State of Minas Gerais (18°55'S, 48°02'W), the rescue staff collected a female of *A. alba* (ca. 55 cm total length). The local macrohabitat is "cerrado," a deciduous and semi-deciduous seasonal dry forest association (Rizzini 1979. Tratado de Fitogeografia do Brasil, Vol. 2, Editora da Universidade de São Paulo, São Paulo. 374 pp.). Upon capture, the female was placed in a wooden collection box (1.0 m x 0.5 m). When the box was opened at 1400 h, two eggs had already been laid. One of us (LBN) observed the remaining 6 eggs being laid between 1554 h and 1835 h. During oviposition, the female maintained an extended position (Fig. 1), and strong contractions of the belly were observed; these progressed in an anterior-posterior direction, like a wave, some for each egg deposited. Deposited eggs were white, essentially equal in size (each measured ca. 3.1 cm x 1.5 cm; Fig. 1). During oviposition, the female displayed neither aggressive nor escape behavior. However, the female became aggressive upon being touched after eggs had been laid, raising her head and tail simultaneously with the mouth opened. Despite the obvious collecting stress, we believe that, when collected, the female was close to oviposition, because at least two other females from the same faunal rescue contained well-developed eggs. Incubation of the eggs described herein was unsuccessful because of fungal infestation. The female was released in appropriate habitat upon completion of observations.

We thank CEMIG (Centrais Elétricas de Minas Gerais) for the financial support and permission to collect the *A. alba* for observation, and Augusto S. Abe and Marc P. Hayes for suggestions on the manuscript.

AMPHISBAENA FENESTRATA (Virgin Islands Amphisbaena). **PREDATION**. Relatively little is known about the biology of many fossorial reptiles and amphibians. For example, almost nothing is known about the predators of any species of *Amphisbaena*. Here we report, for the first time, two cases of predation on *A. fenestrata* observed on Guana Island, British Virgin Islands. In both cases, predation was by the locally abundant colubrid snake *Alsophis portoricensis*.

On 7 October 2001 at 1000 h (air temp. 27.2°C), we captured a male *Alsophis portoricensis* (520 mm SVL, 285 mm TL, mass 52.3 g). It was encountered at an elevation of 160 m near a forest trail on a substrate of dry leaves and small pebbles. The snake was placed in a cloth bag and ca. 30 min later regurgitated a freshly eaten adult *A. fenestrata* (210 mm SVL, 15 mm TL). The specimen was in good condition and was deposited at the Yale Peabody Museum (accession number YPM 12060).

A second predation event was recorded on videotape by Troy Peliwan on 20 October 2001. Around 1800 h, he encountered an *A. portoricensis* attempting to capture and subdue an adult *A. fenestrata*. The snake was first observed on a concrete floor. When disturbed, it moved into the nearby bushes, dragging the *Amphisbaena* with it. Swallowing continued until the snake disappeared, with the prey still in its mouth ca. 10 min later. Both predator and prey were identified from the videotape by GP.

Alsophis portoricensis is known to prey primarily on lizards, though other small vertebrates are also commonly taken (Henderson and Sajdak 1999. *In* Powell and Henderson [eds.], Contributions to West Indian Herpetology: a Tribute to Albert Schwartz, pp. 327–338. Soc. Study Amphib. Rept., Ithaca, New York, 457 pp.). However this is the first record of amphisbaenians in its diet.

We thank L. Lazell and R. Henderson for discussions of these events and the staff of Guana Island for technical assistance. Financial support was provided by The Conservation Agency through a grant from the Falconwood Foundation.

ANOLIS POLYLEPIS (Golfo Dulce Anole). **DIET.** Several studies have shown that vertebrates are rare in the diet of small Neotropical lizards (e.g., Magnusson and Da Silva 1996. J. Herpetol. 27:380–385). Especially little is known about the importance of lizards in the diet of most *Anolis*, a diverse genus with > 400 species having many relatively small (< 60 mm maximum SVL) forms (Pough et al. 2001. Herpetology. 2nd ed. Prentice Hall. New Jersey. 612 pp.). One such small species is *Anolis polylepis*, which reaches a maximum size of 55 mm SVL. *Anolis polylepis*, commonly encountered either on the ground or in low vegetation at heights < 2 m (Leenders 2001. A Guide to Amphibians and Reptiles of Costa Rica. Zona Tropical. Miami, Florida), is known to prey on insects in leaf litter (Leenders, *op. cit.*). Here, we provide the first report of vertebrate prey.

At 1015 h on 20 October 2001, in Golfito National Wildlife Refuge, Puntarenas Province, SW Costa Rica (8°40'N; 83°10'W), we captured a female (41 mm SVL) *A. polylepis* on a tree trunk,

about 60 cm above ground. Upon capture, the female regurgitated a small (29 mm SVL) partially digested anole. We identified it as another *A. polylepis*, so this is the first report of cannibalism in this species.

Some anoles are known to prey on other anoles; some are cases of cannibalism. The latter has been reported in *A. carolinensis* (Jenssen 1993. Herpetol. Rev. 24:58–59) and *A. sagrei* (Nicholson et al. 2000. Herpetol. Rev. 31:173–174). Eleven species of *Anolis* occur in Golfito, including some common ones such as *A. limifrons*, *A. capito*, *A. aquaticus,* and *A. polylepis*. Saurophagy or cannibalism might have implications for studies of territoriality and social behavior in these and other species of anoles (Nicholson et al., *op. cit.*).

Observations were made during a field trip of the herpetology course at the School of Biology, University of Costa Rica (UCR). We acknowledge UCR for support at Golfito, and thank William Eberhard for his suggestions.

LACERTA MONTICOLA (Iberian Rock Lizard). **PREDATION.** *Lacerta monticola* is a small (65–78 mm adult SVL) insectivorous lacertid lizard found mostly in rocky, montane areas of the north and central Iberian Peninsula (Pérez-Mellado 1997. *In* Ramos [ed.], Fauna Ibérica, Vol. 10. Reptiles, pp. 207–218. Museo Nacional de Ciencias Naturales, CSIC, Madrid). In the Sierra de Guadarrama (Central Spain), it is the only lizard species recorded between 1750 and 2350 m elevation. *Lacerta monticola* also shares this habitat with the snow vole, *Chionomys nivalis* (Martín and Salvador 1992. Oikos 65:328–333), a poorly known microtine rodent (40–70 g adult mass) discontinuously distributed from SW Europe to Iran that typically inhabits deep cavities and interstices of rocky habitats (Krapp 1982. *In* Niethammer and Krapp [eds.], Handbuch der Säugetiere Europas, Rodentia II, pp. 261–283. Akademische Verlag, Wiesbaden). No data addressing the relationship of these two species exist. Here, we provide the first report of interaction between *L. monticola* and *C. nivalis*.

Our observations were made during lizard surveys in the "Puerto de Navacerrada" (40°46'N, 04°00'W, Guadarrama Mountains; elevation 2000 m) in July–August 2000. At 1200 h on 13 July 2000, we observed an adult snow vole attack an adult *L. monticola* (~70 mm SVL). After having emerged from a crevice, the vole ran rapidly toward a male *L. monticola* that had been basking on a sunny rock nearby. After a chase lasting a few seconds, the vole managed to grasp the lizard by its tail. The lizard immediately autotomized its tail and fled. The vole took the broken tail, ran to a crevice, and, there, ate the entire tail.

On 13 August 2000 at 1100 h, after the period of emergence of hatchling lizards, we observed a second attack by an adult snow vole. The vole had been walking on the rocks close to a crevice when it detected a *L. monticola* hatchling (~30 mm SVL). Upon detection, it easily captured it after a short rush, and immediately started to eat it by the head.

Adult snow voles were considered to be exclusively herbivorous (Krapp, *op. cit.*). Our observations suggest that predation can be at least facultative. The rigor of environmental conditions in alpine habitats may contribute to explaining why snow voles occasionally prey on lizards, but *Chionomys nivalis* needs study to determine the importance of predation in its overall ecology.

We thank "El Ventorrillo" MNCN Field Station for use of their facilities. Project DGESIC PB 98-0505 to PL and JM, and a predoctoral grant 'Beca per a la Formació de Personal Investigador' 1998FI-00668 (CIRIT) and project DGES PB96-0991 to JJL supported this research.

LEIOCEPHALUS CARINATUS ARMOURI (Northern Curly-tailed Lizard) **OPPORTUNISTIC PREDATION**. Distinctive circumstances can result in opportunistic predation on atypical prey (Woodin and Woodin 1981. Florida Field Nat. 9:64). Here, we document an opportunistic predation event by a great barracuda on a northern curly-tailed lizard, *Leiocephalus carinatus armouri*, in South Florida.

At ca. 0800 h on 22 August 2002, a sunny day with a temperature around 27°C, a ca. 7.5 cm SVL adult lizard was observed sunning 0.3 m above the ground on the smooth, painted seawall above the estuarine canal (the Intracoastal Waterway) near Woolbright Road in Boynton Beach, Florida (26°30'N, 80°03'W). Intimate familiarity with the species, especially the characteristic curl in the tail, revealed the lizard to be a northern curly-tailed lizard, *L. carinatus armouri*, a well-established exotic species in Florida (Weigl et al. 1969. Copeia 1969:841–842). Three anglers, visible from the lizard's position, startled the curly-tail by rapidly approaching its perch from the west. Yet, rather than seek escape by climbing down the seawall to the adjacent ground, the lizard fled down the east side of the seawall and promptly fell 1.5 m down into ca. 0.5 m deep water. After struggling at the water surface no more than 2–3 seconds, the lizard disappeared from the surface in a V-waked noisy splash. A relatively small (ca. 70 cm fork length) great barracuda, *Sphraena barracuda*, could be seen ca. 0.3 m below the surface holding the lizard sideways in its jaws. When the anglers climbed onto the seawall to view the commotion, the barracuda, still with the curly-tail, darted out of view. Observations of the general area continued until about 0805 h, but neither the barracuda nor lizard was seen again.

A breeding population of curly-tailed lizards has existed at the Woolbright Road location since at least 1986, and this species is one of the most common reptiles in the local area (HTS, pers. obs.). Previous observations of northern curly-tailed lizards over many years at this site have shown it to be an agile terrestrial reptile that climbs rough-surfaced hard structures (e.g., cement staircases) with ease and habitually seeks shelter in structural crevices when disturbed. This coupled with unfavorable circumstances of the lizard being startled and the relatively smooth seawall surface presenting a poor surface for purchase likely contributed to this opportunistic predation event.

Submitted by **HENRY T. SMITH**, Florida Department of Environmental Protection, Florida Park Service, 13798 S.E. Federal Highway, Hobe Sound, Florida 33455, USA, and **RICHARD M. ENGEMAN**, National Wildlife Research Center, 4101 LaPorte Ave., Fort Collins, Colorado 80521-2154, USA; e-mail: (RME) Richard.M.Engeman@aphis.usda.gov.

LEPIDOPHYMA GAIGEAE (Gaige's Tropical Night Lizard). **REPRODUCTION.** *Lepidophyma gaigeae* occurs in the Mexican states of Hidalgo and Querétaro (Bezy and Camarillo R. 2002. Contr. Sci., Nat. Hist. Mus. Los Angeles Co. 493:1–41). The sparse reproductive data available describe six females collected in Querétaro: five collected in January had ovulated and one collected in December gave birth to one neonate in March (Dixon et al. 1972. Southwest. Nat. 16:225–237). Here we augment the limited information on reproduction in *L. gaigeae*.

Twenty-one males (mean SVL = 54 mm ± 3 SD, range: 47–59 mm) and 24 females (mean SVL = 55 mm ± 3 SD, range: 50–63 mm) were collected at Durango, Hidalgo, México (20°54' N, 99°14' W) March 1999 to February 2000. Lizards were fixed in 10% formalin, preserved in alcohol, and deposited in the herpetology collection of the Escuela Nacional de Estudios Profesionales Iztacala, Universidad Nacional Autónoma de México.

The left gonad was removed (except for yolk filled follicles or oviductal eggs) and embedded in paraffin. Histological sections were cut at 5 µm, mounted on glass slides and stained with Harris' hematoxylin followed by eosin counterstain. Testis slides were examined to determine the stage of the spermatogenic cycle (recrudescence, primary spermatocytes predominate; spermiogenesis, sperm project into lumina of seminiferous tubules). Ovary slides were examined to determine the stage of the ovarian cycle (inactive, no yolk deposition; vitellogenic, yolk granules present). Enlarged ovarian follicles > 5 mm length or oviductal eggs were counted.

Examination of male monthly samples revealed *L. gaigeae* has a prolonged period of spermiogenesis: March (2) one regressed, one recrudescent; May (1) spermiogenesis; June (3) spermiogenesis; July (3) spermiogenesis; August (1) spermiogensis; October (2) spermiogensis; November (4) spermiogensis; December (1) spermiogensis; January (4) three spermiogensis, one recrudescent. The smallest reproductively active male (spermiogenesis) measured 49 mm SVL.

Examination of monthly female samples indicated *L. gaigeae* begins yolk deposition in late summer and ovulates in winter: March (1) oviductal eggs 2; April (5) oviductal eggs 2, 2, 2, 2, 2; June (1) no yolk deposition; August (4) three no yolk deposition, one yolk deposition; September (1) yolk deposition; October (2) yolk deposition; November (3) yolk deposition; January (3) two oviductal eggs 4, 2, one with 3 enlarged (6 mm) follicles; February (4) oviductal eggs 3, 3, 3, 3. Mean litter size was 2.5 ± 0.7 SD, range: 2–4. No significant correlation existed between ln SVL and ln litter size, $P = 0.14$. The smallest reproductively active female (yolk deposition in progress) measured 50 mm SVL. Although we did not collect neonates, we believe parturition occurs in spring. Méndez-de la Cruz et al. (1999. J. Herpetol. 33:336–339) reported similar timing in the ovarian cycle of *Lepidophyma pajapanensis* from Veracruz, México, where ovulation occurs in March and females give birth by late May or early June.

CAMARILLO-RANGEL,** Laboratorio y Colección de Herpetología, Escuela Nacional de Estudios Profesionales Iztacala, Universidad Nacional Autónoma de México, A.P. 314, Tlalnepantla, Estado de México, México (e-mail: herpetol@servidor.unam.mx).

SAUROMALUS OBESUS (Common Chuckwalla). **ALBINISM.** Albinism in iguanid lizards has been documented for several North American taxa: *Phrynosoma coronatum* (Shaw 1963. Copeia 1963:154), *Sceloporus olivaceus*, and *Sceloporus undulatus* (Hensley 1968. J. Herpetol. 1:92–93). This is the first record of albinism for *Sauromalus obesus*.

On 19 June 2000, two of us (DRT and GTC) observed an adult, albinistic *S. obesus* along the road from Harper Dry Lake through Black Canyon, ca. 200 m northwest of Inscription Canyon and north of Opal Mountain, San Bernardino County, California, USA (35°11'33" N, 117°11'52" W; Fig. 1). The specimen was observed through binoculars at close range (9 m) and its pigmentation was described as "stark white" with a faint pattern that was "off yellow" in color with "white claws." Eye coloration could not be precisely determined, but it appeared dark in an enlarged photograph. Its total length was ca. 60 cm. Other *S. obesus* observed in the area were black to reddish brown in color.

Color slides of this animal were deposited in the Natural History Museum of Los Angeles County (LACM PC 1337–38).

FIG. 1. Albinistic *Sauromalus obesus*, San Bernardino County, California.

SCINCELLA LATERALIS (Ground Skink). **COMMUNAL NEST; EGG AND HATCHLING SIZES.** Reproductive data on *Scincella lateralis* include single clutches with a mode of 3 (range: 1–7; Fitch and Greene 1965. Univ. Kansas Pub. Mus. Nat. Hist. 15:565–575; Johnson 1953. Tulane Stud. Zool. 1:11–27; Lewis 1951. Amer. Midl. Nat. 45:232–240; Mather 1970. Texas J. Sci. 21:429–438). Communal oviposition is reported for other skinks (Young 1988. Catesbeiana 8:34), but is not known in *S. lateralis*. Here I provide the first report of communal oviposition in this terrestrial skink from a site in Bryan, Texas (USA).

While moving sandy loam soil from beneath a china berry tree (*Melia azderac*) on 22 June 2002 at 705 Inwood Drive (30°37'48"N, 96°20'25"W), I encountered a nest of lizard eggs 14 cm below and 74 cm from the base of the tree. Two hatchling ground skinks, 2 collapsed eggshells, and 29 other eggs were in the nest. The length and width of each egg was measured to the nearest 0.1 mm with Vernier calipers, and the eggs were placed in a plastic container with moist vermiculite. The container was maintained in a shaded environment at ambient temperatures. Upon hatching, each hatchling was measured for snout–vent (SVL) and tail length (TL).

The 29 eggs averaged 7.7 mm (range 5.6–9.2 mm) in width; and 10.7 mm (range 9.3–13.6 mm) in length. The egg hatching sequence (number of eggs hatched on each date in parens) was as follows: 22 June (2); 24 June (3); 25 June (2); 26 June (1); 30 June (1); 2 July (2); 3 July (1); 4 July (2); 11 July (2); 12 July (1); 15 July (1); 20 July (1); 23 July (2); 25 July (3). Five eggs did not hatch and developed fungal growth. These were preserved and later opened. Two contained small amounts of yolk, 2 had unpigmented but well-developed embyros, and 1 was a fully formed pigmented embyro ready to hatch. The latter measured 12 mm SVL, 16 mm TL.

Variation in size of the 24 individuals hatched *in vitro* was 17.0–21.0 mm SVL (mean = 19.4 mm); 22.7–31.0 mm TL (mean = 28.8 mm). The 2 hatchlings found in the nest were within the size range of the *in vitro* hatchlings (19 and 20 mm SVL, 25.5 and 27.1 mm TL, respectively), and contained unhealed umbilical scars, suggesting that they just hatched when the nest was discovered.

Fitch and Greene (*op. cit.*) also found that females have a minimum of 22 days between clutches and produce as many as 4 clutches per year. This communal nest may have contained 15 to 26 clutches of eggs based on when the eggs hatched and known variation in clutch size. Moreover, based on the aforementioned intra-clutch interval of 22 days, some females could have laid more than one clutch in the nest.

The study was carried out under Texas Parks and Wildlife Scientific Collecting Permit number SPR 0290-022. Twenty-four of the hatchlings were deposited in the Texas Cooperative Wildlife Collection (TCWC 84866–89).

SERPENTES

ARIZONA ELEGANS ARENICOLOR (Texas Glossy Snake). **DEFENSIVE BEHAVIOR.** The Texas glossy snake (*Arizona elegans arenicolor*) is a poorly known, locally abundant snake in sandy habitats of south Texas (Werler and Dixon 2001. Texas Snakes. Univ. of Texas Press, Austin, Texas. 544 pp.). Three male and two female glossy snakes were captured as part of an ongoing mark-recapture study of Western diamondback rattlesnakes (*Crotalus atrox*) on the Chaparral Wildlife Management Area (Texas Parks and Wildlife Department, La Salle and Dimmit Counties, Texas, USA). The snakes were captured in wire mesh funnel traps placed along 21 drift fence arrays at five sites between 23 June and 19 July 2001. Each snake was sexed and marked by scale clipping the ventral scales. Defensive behavior was also noted for four of these snakes.

Males appeared to be aggressive more often than females, but this was not statistically significant (Fisher's exact test $p = 0.25$). Females exhibited no overt defensive behavior as is typical for this species (Werler and Dixon, *op. cit*; Tennant 1985. A Field Guide to Texas Snakes. Gulf Publishing Co., Houston. 292 pp.). Males exhibited active defense. All three male snakes, prior to removal from the trap, formed an elevated S-coil similar to that of *Crotalus* spp. (Klauber 1997. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. Vol. 1. 2nd Ed. Univ. California Press, Berkeley, California. 740 pp.) and struck and bit repeatedly.

Additionally, upon release, one male moved swiftly and directly to the nearest shrub, a brasil (*Condalia hookeri*), ca. 1.6 m tall and climbed to the end of a branch ca. 1.3 m above the ground. When an attempt to recapture the snake was made, it moved to the end of a limb on the opposite side of the tree. The spiny nature of the shrub prevented recapture.

Active defense in the form of coiling, striking, and biting have not been reported previously for *A. elegans*. This species typically remains motionless and sometimes forms lateral kinks in its body in the presence of humans (Werler and Dixon, *op. cit*). The apparent difference between males and females may be an artifact of sampling but could potentially be the result of elevated testosterone levels, as the period of my observations is consistent with testicular recrudescence (Aldridge 2001. Amphibia-Reptilia 22:243–249).

The active defensive displays could also be an example of Batesian mimicry, where *A. elegans* is mimicking the defensive displays of *C. atrox* as has been suggested between gopher snakes (*Pituophis catenifer*) and western rattlesnakes (*C. viridis*) (Sweet 1985. J. Herpetol. 19:55–67). Predator density appears to be high in the area. Coyotes (*Canis lupus*) and northern caracaras (*Caracara cheriway*) are extremely abundant, with the latter being a known ophiophage (Palmer 1988. Handbook of North American Birds Vol. 5. Diurnal Raptors Part 2. Yale University Press, New Haven, Connecticut. 448 pp.). Additional predators in the area include bobcat (*Lynx rufus*), common raccoon (*Procyon lotor*), American badger (*Taxidea taxus*), and Harris's hawk (*Parabuteo unicinctus*; D. C. Ruthven, pers. comm.).

Escape into thorny shrubs may also be adaptive in this predator-dense environment. My inability to remove the snake from the brasil attests to this. The aggressive coiling and striking could potentially distract the predator long enough to facilitate escape into nearby woody vegetation. I suggest further investigations concerning geographic variation in antipredator behavior and the influence of predator density on selection of antipredator behavior in this species.

I thank Jerry Husak, Dave Duvall (Oklahoma State University),

and Chip Ruthven (Chaparral Wildlife Management Area, Texas Parks and Wildlife Department) for comments that improved the manuscript. The Wildlife Division of Texas Parks and Wildlife Department provided logistical support.

ATRACTUS RETICULATUS (Cobra-de-terra). **PREDATION**. The majority of Brazilian hawks include snakes in their diet (Sick 1993. Birds in Brazil: A Natural History. Princeton University Press, 703 pp.; Rivas and Owens 2001. Herpetol. Review 32:108); however, we are aware of no records of *A. reticulatus* being preyed upon by hawks. On 8 August 2001, we observed a specimen of *Buteo magnirostris* (Falconiformes: Acciptridae) feeding on an adult female specimen of *A. reticulatus* (CEPB/IFSM 123-01; 240.6 mm SVL), on the south bank of the Uruguai River (27°30'06"S, 51°42'52"W), municipality of Machadinho, in the State of Rio Grande do Sul, Brazil. The hawk was perched on a small rock in a pasture and was eating the head of the snake. After 13 min., the hawk flew away leaving most of the posterior part of the snake.

We thank the staff of NATURAE - Projetos e Consultoria Ambiental Ltda. in the Cotiara Faunal Rescue Operation for helping during fieldwork.

Submitted by **IVAN FRANÇA E SOUZA, WILIAN VAZ SILVA, PABLO VINICIUS C. MATHIAS** and **NELSON JORGE DA SILVA JR.**, Laboratório de Herpetologia and Laboratório de Ornitologia, Centro de Estudos e Pesquisas Biológicas, Universidade Católica de Goiás, Ave. Universitária, 1440, Setor Universitário, 74.210-010, Goiânia, Goiás, Brazil (e-mail: souzai@terra.com.br).

BOTHROPS INSULARIS (Golden Lancehead). **DIET**. Accurately determining prey selection and foraging events is essential for a complete understanding of predator foraging ecology and their impact on prey communities (MacGregor and Reinert 2001. Herpetol. Rev. 32:170–172). Some snakes living on small islands have relatively limited sympatric prey items available, and sometimes depend on seasonal bird migrations, e.g. *Macrovipera schweizeri* (Nilson et al. 1999. Amphibia-Reptilia 20:355–375) and *Gloydius shedaoensis* (Sun et al. 2001. Biol. Cons. 97:387–398). On 20 November 2001 (1800 h) at Queimada Grande, a tiny island off the southeastern coast of Brazil (24°28'S; 46°40'W), we discovered an adult *Bothrops insularis* (ca. 60 cm total length) coiled around a freshly-killed adult *Leptotila rufaxilla* (Grey-fronted Dove) on the ground. The head and neck feathers were covered with saliva, evidence that the snake had attempted to swallow the bird. Diameter at the thickest part of the bird's body was ca. 10 cm. However, the prey was apparently too large to be ingested by the snake. Interactions between *B. insularis* and *L. rufaxilla* might be common because this bird is a frequent ground forager and as a result might be highly susceptible to predation. Campos and Mello Filho (1966. A Folha Médica 52:21–44) reported a similar failed feeding attempt on *L. rufaxilla* by *B. insularis*.

Submitted by **MARCELO RIBEIRO DUARTE** and **PAULO SÉRGIO GARRUBO**, Lab. de Herpetologia, Instituto Butantan, Av. Vital Brazil, 1500, CEP 05503-900, São Paulo, SP, Brazil; e-mail (MRD): mrduarte@attglobal.net.

CLELIA PLUMBEA (Mussurana). **NECROPHAGY**. On 23 November 2000, at 2130 h, on a dirt road crossing the coastal plain of Pontal do Ipiranga (19°07'12"S, 39°46'72"W), municipality of Linhares, Espírito Santo state, Brazil, the first author found a female *Clelia plumbea* (61.5 cm SVL; 78.5 cm TTL) with the tail of another snake protruding from its mouth. The *C. plumbea* was immediately collected and placed in a bag, where it promptly regurgitated its meal, a male specimen of the semi-aquatic snake *Liophis miliaris* (49.5 cm SVL; 59 cm TTL). The *L. miliaris* was apparently a road-kill (its body was flattened and appeared to have been run over by a car), which means it was already dead when found by the *C. plumbea*. The *C. plumbea* was subsequently deposited (along with its stomach contents) at the collection of the Museu de Zoologia Mello Leitão (MBLM 729) in Santa Teresa, Espírito Santo, Brazil.

At the time the above event was observed, the entire surrounding pasture area (which is situated on a lower level compared to the road) was flooded, as is typical during the rainy season at this area. We assume that during this period the available habitat area and the food supply for many organisms is reduced, which could favor dietary shifts (such as facultative necrophagy) in some predatory species. Several other snake species have been observed to use the road as their main habitat for foraging during the rainy period in this area (R. L. Teixeira, pers. obs.).

Occasional necrophagy has been previously recorded in a few Brazilian snakes (Sazima and Strussmann 1990. Rev. Brasil. Biol. 50:463–468), as well as in several other species of snakes worldwide (e.g., Bedford 1991. Herpetofauna 21:35–36; Hamel 1996. Herpetol. Rev. 27:43; Mora 1999. Herpetol. Rev. 30:102; Sajdak and Sajdak 1999. Herpetol. Rev. 30:229; Shine 1986. Copeia 1986:424–437). This note adds *C. plumbea* to the list of snake species that can be considered occasional scavengers.

We thank Anibal Melgarejo, Ronaldo Fernandes, and Daniel S. Fernandes for confirming the identification of both snakes, and the Conselho Nacional do Desenvolvimento Cientifico e Tecnológico (CNPq) for the graduate fellowship to the second author (process # 143607-98/7).

CLONOPHIS KIRTLANDII (Kirtland's Snake). **AGGREGATING BEHAVIOR** and **SITE FIDELITY**. Little is known about reproductive cycles or social behavior in *Clonophis kirtlandii*. Most information is anecdotal; a published report of communal denning in *C. kirtlandii* exists (Conant 1943. Amer. Midl. Nat. 29:313–341). Fitch (1970. Univ. Kansas Mus. Nat. Hist. Misc. Pub. 52:1–247) did not mention fall copulation in *C. kirtlandii*, but Ernst and Barbour (1989. Snakes of Eastern North America. George Mason University Press, Fairfax, Virginia. 282 pp.) suggested females may produce more than one litter per year. Minton (2001. The

Amphibians and Reptiles of Indiana. Indiana Academy of Sciences, Indianapolis, Indiana. 404 pp.) mentions a 30 July parturition date, which may indicate fall copulation, and refuge/site fidelity.

At 1410 h on 17 September 2001 we encountered four adult *C. kirtlandii* occupying a single crayfish burrow in Will County, Illinois, USA. The sky was overcast with sporadic light rain and an air temperature of 19.6°C. The site is graminoid-dominated restored prairie with a perched water table and numerous crayfish (*Fallicambarus fodiens, Procambarus gracilis*) burrows. The first snake encountered (adult male, 315 mm SVL, 25.5 g) was found at the surface with ca. 1/3 of its anterior down a 22 mm diameter crayfish burrow. Closer inspection revealed a second snake beneath the first, with its anterior half partially concealed within the burrow. This snake, also an adult male (313 mm SVL, 27.5 g) and the other were removed from the burrow for examination. Upon removal of the two snakes, the head of a third immediately appeared at the burrow entrance. This snake vacated the burrow during observation and was another adult male (320 mm SVL, 28.5 g). After capturing this snake, a fourth *C. kirtlandii* appeared at the burrow opening and slowly began to exit when tapped lightly behind the head by one of us. This snake proved to be an adult female (355 mm SVL, 27.05 g). Temperature in the burrow at a depth of 19 cm was 18°C. The four snakes were retained in the laboratory for data collection and photographs. The female shed her skin in the collecting bag en route to the laboratory. While confined in a 2-1/2-gallon aquarium with paper towel substrate, all three males exhibited courtship behavior, e.g., chin rubbing, frequent tongue-flicks along the female's body, and tail wrapping. When inactive, the snakes coiled in a compact mass under the substrate. The courtship behavior continued intermittently until 21 September, when the four snakes were released at the capture site.

At the same locality in April, two adult female *C. kirtlandii* were found under separate (4 m apart) 1.3 x 1 m corrugated tin sheets positioned to survey snakes. Both were identified by unique dorsal patterns and scale-clipped subcaudals. The first female (374 mm TL, 13 g) found 24 April was not recaptured, but the second (250 mm SVL, 9.5 g) found 25 April, was found under the same cover panel on 26, 27, and 30 April. Similar observations occurred previously (D. Mauger, unpubl. data), however four *C. kirtlandii* found under cover panels on successive days from April to June 1996 were not marked; it was therefore unknown whether they represented one or more individuals.

We thank the Illinois Department of Natural Resources for Scientific Collecting Permit No. A01.0132 issued to TGA.

CROTALUS ATROX (Western Diamondback Rattlesnake). **BEHAVIOR**. Most observations of agonistic behavior between conspecific male snakes have been made during the mating season and have been interpreted as competition "for priority of access to females" (Schuett 1994. Zoo Biol. 15:209–221). Schuett (*op. cit.*) proposes that "there is little evidence that fights in nature occur over space (territories) or food."

Here, we report two observations of male-male fighting from upland Sonoran desert, 22 km E of Carefree, Arizona, USA, in Camp Creek Wash (33°47'N, 11°45'W, 671 m) on the Tonto National Forest. At 0930 h on 15 October 1998 two *C. atrox* (both > 1200 mm SVL) were observed fighting. Fighting continued for ca. 2 min. before the pair, disturbed by the observer's (BLS) presence, disengaged and attempted to retreat into adjacent vegetation. Extensive tracks in the sandy wash suggest a lengthy engagement prior to observation. On 3 November 1998, at 1540 h, two *C. atrox* (both ca. 900 mm SVL) were observed fighting for ca. 1 min. before the pair, disturbed by the observer's (BLS) presence, disengaged and retreated into a *Neotoma albigula* midden. In neither case was a female snake found on the surface, though it is possible a female may have been present in nearby refugia. In addition to our observations, late season male-male fighting has been reported on 6 December in a Texas population (Klauber 1972. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. Univ. of California Press, Berkeley. 1533 pp.) and a photograph of fighting that appears in Lowe et al. (1986. The Venomous Reptiles of Arizona. Arizona Game and Fish Department, Phoenix. 115 pp.) was taken on 29 October (Brent Martin, pers. comm.). In upland Sonoran desert of central and southern Arizona, *C. atrox* often overwinter in rocky retreats (or *N. albigula* middens) on hillsides or along dry washes (ATH, radiotelemetric observations). Here, *C. atrox* typically exhibit a flurry of mating and male-male fighting in March–April at or near the den site, usually prior to egress (Roger Repp, pers. comm.). Mating and male-male fighting also occur September–October (Lowe et al., *op cit.*). Although males have been observed with females in November (Roger Repp, pers. comm.), the latest date of confirmed copulation is 15 October (Gordon Schuett, pers. comm.). On warm days in winter, male *C. atrox* occasionally make short movements between refugia (ATH, radiotelemetric obs.). Thus, although it is probable our observations are of males fighting for access to females late in the fall mating period, considered collectively, they raise the possibility that from November through February, males might be competing for primary access to refugia occupied by females that will be receptive upon emergence in spring.

CROTALUS CATALINENSIS (Santa Catalina Island Rattleless Rattlesnake). **REPRODUCTION**. *Crotalus catalinensis* is endemic to Isla Santa Catalina (25°39'N, 110°49'W), Baja California Sur, Mexico. The biology of this species was summarized by Beaman and Wong (2001. Cat. Am. Amphib. Rept. 733.1–733.4). Information on *C. catalinensis* reproduction is in Grismer (2002. Amphibians and Reptiles of Baja California Including its Pacific Islands and the Islands in the Sea of Cortés, University of California Press, Los Angeles, xiii + 399 pp.). The purpose of this report is to present information on the testicular and ovarian cycle from

a histological examination.

Reproductive data are presented from six *C. catalinensis* collected from 1962–1974. The posterior portion of each snake was opened by a mid-ventral incision to expose the gonads. The left ovary or left testis and vas deferens were removed for histological examination. Gonads were dehydrated in a graded series of ethanol, cleared in toluene and embedded in paraffin. Histological sections were cut at a thickness of 5 µm, mounted on slides and stained with hematoxylin and eosin counterstain. Oviductal eggs from one pregnant female were measured and counted (histological examination of the eggs was not performed).

Three females collected 27 April (San Diego Society of Natural History, SDSNH 48020, SVL 753 mm), 24 June (California Academy of Sciences, CAS14000, SVL 560 mm), and 25 June (SDSNH 53052, SVL 540 mm) did not exhibit yolk deposition (= secondary vitellogenesis *sensu* Aldridge 1979. Herpetologica 35:256–261). One female (SDSNH 44353, SVL = 662 mm) collected 19 April contained four oviductal eggs (12–16 mm length). The presence of non-vitellogenic females during the reproductive season suggests that not all females are reproductively active every year. Frequency of reproduction in rattlesnakes is apparently variable with some populations producing litters each year (Fitch 1985. Misc. Pub. Mus. Nat. Hist., Univ. Kansas 76:1–76; Fitch and Pisani 1993. Univ. Kansas Occas. Pap. Mus. Nat. Hist. 156:1–24). Biennial, triennial, or quadraennial cycles may occur within the same species (Ernst 1992. Venomous Reptiles of North America. Smithsonian Institution Press, Washington, 236 pp.). Yearly percentages of pregnant females appear related to food abundance (Goldberg and Rosen 2000. Texas J. Sci. 52:101–109). While gravid *C. catalinensis* have been observed from mid-July to early August, with one female having five early-developing embryos, neonates have been observed during mid-August with a female collected in early August producing two young (Grismer, *op. cit.*). Cliff (1954. Trans. San Diego Soc. Nat. Hist. 12:67–98) reported that a sexually mature female collected in March had not ovulated, however, it was not stated if the follicles were enlarged.

Two males were examined. The testis from one male, (SDSNH 44353, SVL = 698 mm) collected 19 April was in recrudescence. Sertoli cells, spermatogonia, and primary spermatocytes were present, while the vas deferens contained sperm from the previous spermiogenesis. The second male (University of Kansas, Museum of Natural History, KU 159591, SVL = 750 mm), collected 27 August, was undergoing spermiogenesis. Clusters of metamorphosing spermatids lined the seminiferous tubules. The vasa deferentia contained sperm. These observations suggest the testicular cycle of *C. catalinensis* is similar to that of other North American rattlesnakes (Goldberg 1999. Texas J. Sci. 51:31–36; Goldberg 2000. West. N. Am. Nat. 60:98–100; Goldberg and Rosen, *op. cit.*), which have a summer–autumn period of sperm production (spermiogenesis) followed by a spring-early summer period of regression and renewal (recrudescence) for the next period of spermiogenesis.

We thank Bradford Hollingsworth (SDSNH), John Simmons (KU), and Jens Vindum (CAS) for permission to examine specimens.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA and **KENT R. BEAMAN,** Section of Herpetology, Natural History Museum of Los Angeles County, 900 Exposition Boulevard, Los Angeles, California 90007, USA.

CROTALUS PRICEI (Twin-spotted Rattlesnake). **WINTER ACTIVITY**. We tracked three *Crotalus pricei* (two males and one female) monthly using implanted temperature-sensitive radiotransmitters during September 1997–April 1998 in Arizona's Chiricahua Mountains, USA (elevation range = 2530–2700 m). For reference, mean temperature at 1.5 m above ground (T_{air}) between 20 November 1998 and 20 February 1999 was 5.8°C at the lowest elevation site. At least one snake was visible during each tracking period in all months except February, when we were unable to access the area because heavy snowfall.

In mid- to late October, the two males moved from talus slopes where they had spent the previous months to new talus slopes. Each selected relatively warm locations near the edge of the talus slope where snowmelt was rapid. At one of these sites on 15 December, the substrate (talus) temperature (T_s) was 41.6°C (T_{air} = 15.6°C).

The female snake spent the winter off talus. Like the males, she moved into her winter area in mid-October. She remained in a location densely vegetated with ground cover (mostly *Eriogonum jamesii*) until at least mid-December. From mid-January to mid-March, she was under a surface rock.

The female snake moved at least 11.1 m between 15 December and 13 January. One of the male snakes moved 7.5 m during November, and the other moved at least 1.2 m every month. We never observed conspecifics near radiotelemetered animals in the winter, suggesting that they overwintered singly.

Body temperature (T_b), T_{air}, and T_s were recorded when snakes were located (range = 0922–1538 h). Between November–April, T_b averaged (mean ± SE) 18.5 ± 2.2°C (N = 13, range = 5.0–29.8°C). T_s at *C. pricei* locations was substantially warmer than T_{air} ($T_s - T_{air} = 7.12 \pm 2.21$°C); T_b did not differ significantly from T_s ($T_b - T_s = -1.02 \pm 2.54$°C). Mean T_b of *C. pricei* during December–February (16.1 ± 3.2°C) was slightly higher than T_b reported for *C. atrox* and *C. tigris* during the same months at much lower elevations (689–756 m) in Arizona (Beck 1995. J. Herpetol. 29:211–223).

This research was funded by an IIPAM grant (I97040) from the Arizona Game and Fish Department (AGFD) Heritage Fund. All animals were handled under AGFD Scientific Collecting Permits and an IACUC-approved protocol. We thank D. Swann, C. Goldberg, and J. Lovich for helpful comments.

CROTALUS TRANSVERSUS (Cross-banded Mountain Rattlesnake). **ENDOPARASITES.** The cross-banded rattlesnake, *Crotalus transversus* is known only from Distrito Federal and Morelos, México (Flores Villela and Gerez 1994. Biodiversidad y Conservación en México: Vertebrados, Vegetacíon y Uso del Suelo, Comision Nacional para el Conocimiento y Uso de la Biodiversidad y Universidad Nacional Autónoma de México, Ciudad

Universitaria, México, D.F., 439 pp). There are, to our knowledge, no reports of endoparasites from this species. The purpose of this note is to report a nematode species from *C. transversus*.

One adult female *C. transversus* was collected July 1998 in the vicinity of Presa Iturbide (19°31'N, 99°30'W), State of México, México. It was maintained in captivity until October 1999 and released. Feces were collected, preserved in 95% ethanol, and later examined with a dissecting microscope. Two female nematodes were found, placed separately on a glass slide and cleared in a drop of concentrated glycerol. Each nematode was found to possess the bivalved buccal cavity characteristic of the genus *Kalicephalus*. Further examination revealed the nematodes to be prodelphic (ovaries parallel and anterior to vulva), to possess a rounded esophagus with the excretory pore at the level of greatest esophageal width, and to have a breviconical tail with a terminal spike. These characteristics are consistent with the description of *Kalicephalus costatus* as provided by Schad (1962. Can. J. Zool. 40:1035–1065). The nematodes were placed in a vial of 70% ethanol and deposited in the United States National Parasite Collection, USNPC, Beltsville, Maryland as USNPC 91754.

Although *K. costatus* is world-wide in distribution and has been reported in a variety of snake species from North and South America (Baker 1987. Mem. Univ. Newfoundland, Occas. Pap. 112:1–325), it is known from only one other rattlesnake, *C. durissus* (Schad, *op. cit.*). *Crotalus transversus* is a new host record and Mexico is a new locality record for *K. costatus*.

DRYMARCHON CORAIS COUPERI (Eastern Indigo Snake). **COMBAT RITUAL.** The eastern indigo snake (*Drymarchon corais couperi*), a large colubrid native to the southeastern United States, breeds from October through February, with a peak in breeding between mid-November and late December (based on reproductive behavior in captivity) (Speake et al. 1987. *In* Odom et al. [eds.], Proc. Third Southeast Nongame and Endangered Species Symposium, pp. 84–88. Georgia Dept. Nat. Resour. Game and Fish Div., Atlanta, Georgia). Aggressive behavior between male Eastern Indigo Snakes during the breeding season might lead to combat or cannibalism (Moler 1992. *In* Moler [ed.], Rare and Endangered Biota of Florida – Vol. 3: Amphibians and Reptiles, pp. 181–186. Univ. Press of Florida, Gainesville, Florida). Here I describe a combat ritual between two adult male indigo snakes observed under field conditions.

On 20 November 2000 at 1230 h (weather clear, sunny, slight breeze, air temperature 14°C; overnight low on 19 November was 6°C) I discovered a pair of adult Eastern Indigo Snakes together near the entrance to an abandoned, adult-sized Gopher Tortoise (*Gopherus polyphemus*) burrow in Evans County, Georgia, USA. From a distance of 6 m, the snakes were observed continuously for the next 10 min. I then captured both snakes; later the same day they were measured, probed to determine sex, and marked as part of an ongoing mark-recapture study. Both snakes were males (169 cm SVL/2.96 kg; 183 cm/3.41 kg). The larger male was subsequently found on the surface near an adult female indigo snake—at a tortoise burrow 471 m to the north—on 29 January 2001.

The entire time the snakes were observed together, the anterior portions of their bodies were entwined and both snakes were in constant motion; the tails of both snakes extended into the tortoise burrow. During most of my observation, the heads of both snakes were lifted vertically 30–60 cm above the ground, often swaying in tandem; by pressing with their chins/necks, each snake attempted to force the other snake toward the ground ("topping" as described by Gillingham 1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 184–209. Macmillan Publishing, New York). On several occasions both snakes toppled to the ground, only to again soon elevate. Although biting might occur during Eastern Indigo Snake combat under captive conditions (D. Alessandrini, pers. comm.), biting was never observed. Gillingham (*op. cit*) mentions that biting, when exhibited, is of short duration and occurs just prior to the end of a combat encounter. In this instance, I interrupted by capturing the snakes before the conclusion of their combat encounter.

This indigo snake study is being conducted with the permission of the Georgia Department of Natural Resources (Scientific Collecting Permit 29-WMB-00-132).

Submitted by **DIRK J. STEVENSON**, Fort Stewart Fish and Wildlife Branch, Directorate of Public Works, 1113 Frank Cochran Drive, Fort Stewart, Georgia 31314-4940, USA; e-mail: stevensond@.stewart.army.mil.

GOMESOPHIS BRASILIENSIS (NCN). **REPRODUCTION** and **DIET.** *Gomesophis brasiliensis* is an aquatic, Brazilian endemic snake and is a member of tribe Tachymenini (Amaral 1932. Memórias do Instituto Butantan 52:91–92; Bailey 1967. Herpetologica 23:151–161). Aside from scarce and conflicting statements (see Amaral 1932, *op. cit.*; Amaral 1978. Serpentes do Brasil. Melhoramentos/Univ. São Paulo, Brazil, 246 pp.) no information is available on the biology of this snake. We present herein data on sexual dimorphism, mode of reproduction, reproductive cycle and food habits based upon the dissection of 71 specimens from southeastern and southern Brazil housed in the collection of the Instituto Butantan (IB).

Sexual maturity is attained at similar snout–vent lengths (SVL) in males and females: adult males averaged 355.6 mm (SD = 60.8, range 267–455 mm, N = 27) and females averaged 337.0 mm (SD = 53.7, range 261–475 mm, N = 27). There were no significant differences in SVL and relative head size between sexes (SVL: $U = 289$, $p = 0.270$, N = 54; head size: t-test of residuals: $t = 0.45$, $p = 0.656$, N = 48).

Gomesophis brasiliensis is a live-bearer as already recorded for other members of Tachymenini (Ferrarezzi 1994. *In* Nascimento et al. [eds.], Herpetologia do Brasil 1, pp. 81–91. Fundação Biodiversitas and Ezequiel Dias. Belo Horizonte). Females with vitellogenic follicles appeared from August to February (Fig. 1). Three females with oviductal embryos were collected in December (N = 1) and March (N = 2) (Fig. 1). Eight presumed hatchlings (112–123 mm SVL) were collected in February and March. Thus,

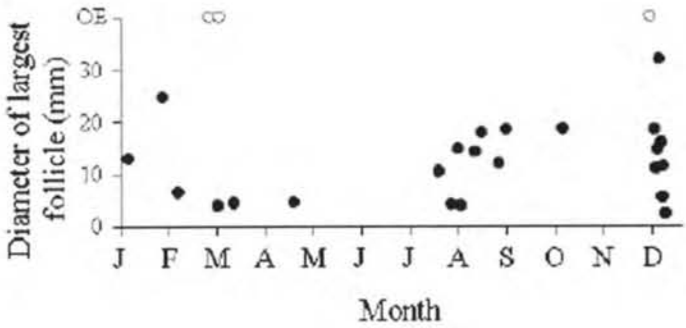

FIG. 1. Seasonal variation in the diameter of the largest ovarian follicle in adult *Gomesophis brasiliensis* females. Open circles represent oviductal embryos.

the reproductive cycle of *G. brasiliensis* is seasonal, with vitellogenesis and gestation occurring throughout the rainy season and recruitment of juveniles at the end of rainy season and onset of the dry season.

Eleven specimens had earthworm chetae in their hindguts. A suggestion was made that *G. brasiliensis* preys on earthworms and insects (Amaral 1932, *op. cit.*), but later Amaral (1978, *op.cit.*) stated that *G. brasiliensis* prey on lizards and small rodents. Our data indicate that *G. brasiliensis* feed primarily if not exclusively on earthworms, and thus the number of goo-eaters (Greene and Cadle 1994. *In* Ricklefs and Schluter [eds.], Species Diversity in Ecological Communities—Historical and Geographical Perspectives, pp. 281–293. Univ. of Chicago Press. Chicago and London) within xenodontine snakes is here increased by one genus. In the Neotropics, species in the genera *Atractus* and *Sordellina*, *Liophis breviceps*, and now *G. brasiliensis* are known to feed largely on earthworms (Greene and Cadle, *op. cit*; Marques 1996. Herpetol. Rev. 27:147; Martins and Oliveira 1999. Herpetol. Nat. Hist. 6:78–150). Most species of Tachymenini feed on frogs and lizards, but *Tomodon ocellatus*, *T. dorsatus*, and *G. brasiliensis* regularly prey on invertebrates (Gallardo 1972. Neotropica 18:57–63; Bizerra 1998. História Natural de *Tomodon dorsatus*. M.S. dissertation. Univ. São Paulo, São Paulo, SP. 102 pp.; present study). A study on phylogenetic relationships within the tribe Tachymenini (Bizerra, *op. cit.*; Franco 1999. Relações filogenéticas entre os gêneros da tribo Tachymenini Bailey, (1967) (Serpentes; Colubridae). Ph.D. thesis. Univ. São Paulo, São Paulo, SP., 252 pp.) indicates that diet based on invertebrates is a derived character in this group.

We thank I. Sazima for incentives and suggestions on this manuscript and A. M. Mazzoni and C. C. Nogueira for suggestions. We thank M. F. Furtado and V. Germano (IB) for allowing dissection of snakes under their care. Financial support was provided by the FAPESP (00/12339-2).

LEPTOTYPHLOPS HUMILIS HUMILIS (Southwestern Blind Snake). **BEHAVIOR and POSSIBLE DIET.** Blind snakes are known to feed on the larvae of various ant and termite species, but specific hymenopteran or isopteran species are rarely reported. On 22 June 2000 at 2130 h in the boulder fields surrounding Cataviña, Baja California, México, an adult *L. h. humilis* (273+11 mm) was found immediately adjacent to a series of ant burrows. The snake was captured as it was burrowing its head into the loose sand around a burrow entrance as well as into the entrance itself. The snake was quickly measured and released at the site of capture, with the snake escaping rapidly into the burrow. No ants were seen exiting the burrow, but winged alates were seen at the burrow entrance just after the snake's capture. In the morning of 23 June, several ants were present and identified as *Pogonomyrmex californicus* (Buckley). The burrowing behavior of the snake might have been an attempt by the snake to gain chemosensory information regarding the identity of the inhabitants of the burrow or might have represented the final movements after ingestion of a hymenopteran prey.

Submitted by **TRAVIS J. LaDUC**, Section of Integrative Biology, 1 University Station C0930 and Texas Memorial Museum, The University of Texas, Austin, Texas 78712-0253, USA (e-mail: travieso@mail.utexas.edu), and **VERONICA LaDUC**, 7812 Copano Drive, Austin, Texas 78749, USA.

MASTICOPHIS FLAGELLUM TESTACEUS (Western Coachwhip). **CANNIBALISM.** The diets of *Masticophis flagellum* include lizards, small mammals, birds, bird eggs, snakes, insects, and small turtles (Wright and Wright 1957. Handbook of Snakes of the United States and Canada. Cornell Univ. Press, Ithaca. 2 vol., 1105 pp; Werler and Dixon 2000. Texas Snakes. Univ. Texas Press, Austin. 437 pp.). Cannibalism in captivity has been reported several times for this species (for review see Mitchell 1986. SSAR Herpetol. Circ. 15:1–37), but only once before in the field, with the field observation limited to a single line, "Another [*M. flagellum*] was caught while swallowing another small coachwhip" (Guidry 1953. Herpetologica 9:49–56). This note provides a second, more detailed, account of cannibalism in this species.

On 27 August 1999, we found a road-killed *M. flagellum* (TNHC 60252: 860+300 mm; 225.26 g [without prey item]) on FM 2050, 3.6 rd mi S U.S. Hwy 59 (USA: Texas: Webb Co.) at 2108 h. Upon preserving the specimen the following morning, a smaller *M. flagellum* (TNHC 60253: 455+150 mm; 35 g) was found inside the larger snake, anterior of the snake's stomach. The smaller *M. flagellum* did not appear to have any vehicle-induced wounds, but we are unsure whether it was alive or dead when consumed (head-first) by the larger individual.

Submitted by **TRAVIS J. LaDUC**, Section of Integrative Biology, 1 University Station C0930 and Texas Memorial Museum, The University of Texas, Austin, Texas 78712-0253, USA (e-mail: travieso@mail.utexas.edu), and **VERONICA LaDUC**, 7812 Copano Drive, Austin, Texas 78749, USA.

NERODIA SIPEDON PLEURALIS (Midland Water Snake). **REPRODUCTION.** In southeastern Mississippi, *Nerodia sipedon pleuralis* is the most abundant snake associated with the upper Pascagoula River System, which consists of the Leaf and Chickasawhay Rivers and tributaries thereof. Although *N. sipedon* has been extensively studied in the northern and central portions of its distribution, few studies have been conducted on this species from the southern extremity of its distribution, and data are lacking on reproduction from *N. sipedon* in Mississippi. In Alabama, *N. sipedon* bears 12–30 young from July to early September (Mount 1975. The Reptiles and Amphibians of Alabama. Auburn, Alabama. 347 pp.).

As part of a study that required the use of neonatal snakes, gravid females of *N. sipedon* were collected from the Leaf River in Forrest and Jones Counties, Mississippi, USA, during the first week of July (nine individuals each collected in 1999 and 2001). These snakes were maintained in captivity until they gave birth, and were thereafter released at their capture sites. Snakes collected in 1999 and 2001 gave birth from 5 July to 12 July and from 25 July to 10 August, respectively. Data (expressed as means ± 1 SE) collected from these snakes (N = 18) were the following: prepartum mass (g) = 245.2 ± 15.9 (177.6–436.7), postpartum mass (g) = 171.3 ± 12.5 (111.4–319.1), number of offspring = 15.3 ± 0.8 (10–22), and relative clutch mass (RCM) = 30.5 ±.1.5 (19.6–37.3). A correlation analysis indicated a significant positive relationship between prepartum mass (g) of snakes and the number of offspring they produced ($t = 3.231$, $df = 16$, $P = 0.005$; Fig. 1).

Relative to *N. sipedon* in Alabama, snakes from this study produced very small litters early in the birthing season. In fact, the 10 offspring produced by an individual of *N. sipedon* from this study is among the smallest litter size published for this species, with the exception of *N. s. insularum*, which may bear as few as six young (Camin and Ehrlich 1958. Evolution 12:504–511). However, although *N. s. insularum* attains a total length that is comparable to that of *N. s. pleuralis* (56–145 cm versus 61–150 cm [Tennant and Bartlett 2000. Snakes of North America. Eastern and Central Regions. Gulf Publ. Co., Houston, Texas. 588 pp.]), the former taxon may bear far more young (50 versus 30 [King 1986. Copeia 1986:757–772]). Thus, as is typical for most other widespread species of reptiles whose reproductive patterns have been studied in different climates, it appears that individuals of *N. sipedon* from warmer climates produce fewer offspring than do individuals from cooler climates. Further studies on the demography of *N. sipedon* in southeastern Mississippi are needed to determine if the small litter size is offset by an earlier age at maturation or a larger size of individual offspring.

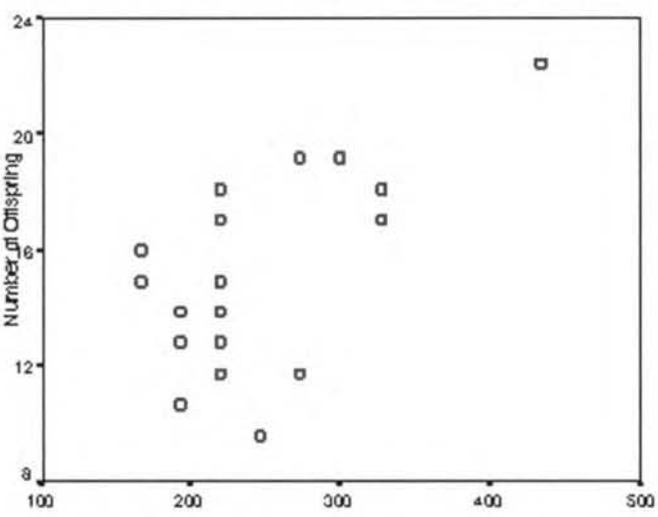

FIG. 1. Scatter plot of the prepartum mass of gravid *Nerodia sipedon* (N = 18) and the number of offspring they produced.

Submitted by **JOHN G. HIMES** and **DAVID C. BECKETT**, Department of Biological Sciences, Box 5018, University of Southern Mississippi, Hattiesburg, Mississippi 39406, USA; e-mail (JGH): John.Himes@usm.edu; (DCB): David.Beckett@usm.edu.

OPHIOPHAGUS HANNAH (King Cobra). **JUVENILE DIET**. Although the diet of *Ophiophagus hannah* is known to constitute snakes and large lizards, especially varanids (David and Vogel 1996. The Snakes of Sumatra. An Annotated Checklist and Key with Natural History Notes. Edition Chimaira, Frankfurt am Main, 260 pp.; Smith, 1943. The Fauna of British India, Ceylon and Burma, Including the Whole of the Indo-Chinese Region. Vol. III. Serpentes. Taylor and Francis, London, xii + 583 pp.), and no specific information is available for the diet of juveniles. A hatchling *O. hannah* from the village of Webbi, near Mayabunder, Middle Andaman Island, Bay of Bengal, India, that was collected on 25 July 2001 as a road kill (USDZ 2.5176; 400.5 mm SVL), contained a recently- ingested juvenile *Lycodon capucinus* (USDZ 2.5177; 255 mm SVL, body width 8.1 mm, and tail length 54 mm). The prey was swallowed head-first.

We thank the Andaman and Nicobar Islands Environmental Team for support of field researches and collection from the Andaman Islands, Alok Saxena and Mr. Ghramduhari of the Andaman and Nicobar Forest Department for permission and facilities, Harry Vasanth Andrews for encouragement, and Kelvin Kok Peng Lim (USDZ) for curatorial assistance.

PSEUDECHIS PORPHYRIACUS (Red-Bellied Black Snake). **DIET**. The 1935 introduction and subsequent rapid spread of the toxic giant toad (*Bufo marinus*) in Queensland, Australia is well-documented (Sabath et. al. 1981. Copeia 1981:676–680; Easteal et. al. 1985. J. Herpetol. 19:185–188). It has been suggested that apparent density and range declines in anurophagous reptiles (especially varanid lizards and snakes) are directly attributable to attempted predation on *B. marinus* (Covacevich and Archer 1975. Mem. Qld. Mus. 17:305–310), including *P. porphyriacus* in north Queensland (Shine and Covacevich 1983. J. Herpetol. 17:60–69). Such claims are unsubstantiated and recent attempts to quantify this phenomenon have failed to find any direct impact on anurophagous reptiles by *B. marinus* (Catling et. al. 1999. Wildlife Res. 26:161–185). Dead snakes with partially ingested toads

in their mouths have been found throughout the range of *B. marinus* in Queensland (Covacevich and Archer, *op. cit.*) but when viewed in perspective, such finds are comparatively rare.

I have collected data from > 2000 snakes from coastal sub-tropical and tropical Queensland over a nine-year period and have found no evidence of predation on *B. marinus* or of population declines that can be attributed to it. In suitable habitat anurophagous snakes are common, regardless of *B. marinus* densities and it appears that snakes largely ignore *B. marinus* as a prey resource. A well-known exception is the colubrid *Tropidonophis mairii,* which includes metamorph *B. marinus* in its diet but has been recorded to die after ingesting comparatively large specimens (Ingram and Covacevich 1990. Mem. Qld. Mus. 29:396). A similar pattern has been recorded for the toxic native frog *Litoria dahlii* in northern Australia. This frog is ignored as a prey item by all snakes except *T. mairii* (Madsen and Shine 1994. Wildlife Res. 21:21–25). Native Australian fishes rapidly learn to avoid toxic *B. marinus* larvae within one day of their initial encounter (Crossland 2002. J. Fish Biol. 59:319–329), and it would be anticipated that reptiles may exhibit similar behavior.

On 6 June 2001 at 1525 h, a large adult male *P. porphyriacus* (1031 mm SVL, 600 g) was found freshly dead in *rigor mortis* directly below the Kareeya Power Station beside the Tully River, Tully Gorge, northeast Queensland, Australia (17°45.988'S, 145°34.640'E). Assuming the snake to have been killed by power station staff, I made inquiries and learned that it was found active but 'groggy' within the station grounds at noon the previous day. It was carried to the edge of the river and released several meters from where I discovered its body. Palpation of stomach contents revealed two intact sub-adult *B. marinus* (Fig. 1) (61 mm snout–ischium length [SIL], 20.5 g; 54 mm SIL, 12 g). This case is interesting because the snake was able to capture and ingest, to stomach level, two relatively large *B. marinus* and survive > 24 h.

Toxin levels in *B. marinus* are known to increase ontogenetically (Crossland 1998. Herpetologica 54:364–369) and I suggest that occasionally individual snakes that are in the habit of ingesting metamorph *B. marinus* (perhaps because of intraspecific variation in resistance to *B. marinus* toxins), swallow larger specimens

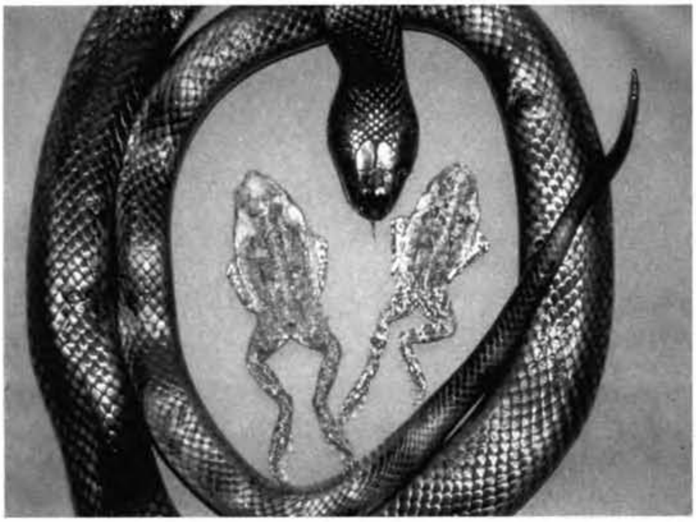

FIG. 1. Adult *Pseudechis porphyriacus* with two sub-adult *Bufo marinus* palpated from its stomach. The snake died 24 h after ingestion of the toads.

with high toxin levels sufficient to kill the snake. I cautiously suggest that, at least in the Tully area, *P. porphyriacus* may be successfully ingesting metamorph *B. marinus*. It is difficult to account for the events described in any other way. Both *P. porphyriacus* and *B. marinus* are common in Tully Gorge and have occurred sympatrically for > 60 yrs (Sabath et. al., *op. cit.*). I urge field biologists active in north Queensland to examine gut contents of *P. porphyriacus* whenever the opportunity arises, to ascertain if *B. marinus* is beginning to become a part of the diets of these snakes. Shine (1991. Copeia 1991:120–131) suggests that the impression that *Tropidonophis* is unusual in eating toads might reflect the abundance of this snake (relative to sympatric anurophagous elapids and pythons) in many of the habitats in which toads also are common, and hence the higher probability of observing predation on *B. marinus* by *Tropidonophis* than by other snake species.

The snake (QMJ76648) and toads (QMJ76649-50) are deposited in the Queensland Museum.

Submitted by **SIMON FEARN**, School of Biological Sciences, James Cook University, Townsville, Queensland, Australia, 4811; e-mail: simonfearn@iprimus.com.au.

RHINOCHEILUS LECONTEI (Long-Nosed Snake). **ALBINISM**. *Rhinocheilus lecontei* has a large geographic range, extending from the southwestern United States through much of northern México. There is a single report of albinism for this species based on a specimen collected in Durango, México (Hendricks 1974. J. Herpetol. 8:185), and no records of albinism for the U.S. portion of the range. On 19 August 2001 at 2130 h, we found a hatchling female *R. l. tessellatus* crossing a paved road in Presidio County, Texas, USA. The specimen has pink irises and a complete lack of black pigment (Fig. 1).

FIG. 1. Hatchling albino female *Rhinocheilus lecontei tessellatus* shown with a normally pigmented male specimen for comparison.

NORRIS**, Stanford University School of Medicine, Stanford University Medical Center, 701 Welch Road, Suite C, Palo Alto, California 94304, USA (e-mail: bob.norris@stanford.edu), and **MICHAEL BERARDI**, 9526 Amber Dawn, Helotes, Texas 78023, USA (e-mail: txherper@aol.com).

THAMNOPHIS MARCIANUS (Checkered Garter Snake). **SALVAGING PRENEONATES FROM A ROAD-KILL.** The results of salvaging unborn or preneonate young of natricine snakes from road-killed gravid females does not seem to be recorded in the literature. Pope (1952. Snakes Alive and How They Live. The Viking Press, New York. 238 pp.) suggested that the young of a gravid female live-bearing snake, cut open a few days before normal birth, would survive, and that snakes are often killed with enough force to set any well developed young free. Oliver (1955. The Natural History of North American Amphibians and Reptiles. V. Van Nostrand Co., Princeton, New Jersey. 359 pp.) agreed, commenting that if a female carrying young about to hatch, was vigorously clubbed, her swollen body might burst, releasing the young. Accounts of unborn young surviving their mother's death are exemplified by J. T. Burkhart (pers. comm.) who related an account of a *Thamnophis* sp. being run over by a vehicle, expelling numerous young that subsequently crawled away.

This is a report on salvaging preneonate young from a road-killed checkered garter snake, *Thamnophis marcianus*. The specimen was collected from Willow Road in extreme northwestern Enid, Garfield County, Oklahoma, USA at 2059 h (after dark) on 29 September 1995. Abdominal movement was observed in the snake that did not seem to be characteristic reflex action. The snake was hurriedly opened surgically at 2110 h, and 25 preneonate young were removed by 2233 h. Seven young exhibited life signs such as mouth gaping, tongue flickering, and body movements.

The total length of the parent female was 65.5 cm. (SVL 51.2 cm, tail 14.3 cm). Three of the 25 young were accidentally mutilated during hasty surgery, and were not measurable, another remained in its embryonic sac and was not measured. Total lengths of 21 remaining young varied from 15.1 to 20.4 cm, averaging 17.9 cm. Total lengths of the five surviving live young was 17.0 to 20.4 cm, averaging 10.04 cm. Three of these died by 23 December 1995. Two remaining juveniles have survived.

Specimens were deposited in the museum collections of St. Gregory's University, Shawnee, Oklahoma, SGU numbers 510 (adult female), and young 511–528, 534, 560 and 2038.

Herpetological Review

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

Society for the Study of Amphibians and Reptiles

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2003 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with VISA or MasterCard (account number and expiration date must be provided). Payment should be sent to: Theodora Pinou, SSAR Treasurer, Peabody Museum of Natural History, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Fax: (203) 432-5176; e-mail: theodora.pinou@yale.edu

Future Annual Meetings

2004 — University of Oklahoma, Norman, Oklahoma, 26–31 May (with ASIH, HL)
2005 — University of South Florida, Tampa, Florida (with ASIH, HL)

SSAR BUSINESS

SSAR to Auction Herpetological Library of Sherman A. Minton, Jr., M.D.

Sherman A. Minton, Jr., who died in 1999, was a leading expert on venomous snakes and the herpetology of Pakistan and of his native Indiana, and on each topic he wrote landmark volumes. He was Professor of Microbiology and Immunology at the Indiana University Medical School in Indianapolis for most of his long and productive career. He held many elected positions in several national and international herpetological and toxinological societies, including the presidency of SSAR in 1986. A warm remembrance of Sherman was published in *Herpetological Review* (vol. 30, no. 4, pp. 202–204, 1999), written by his long-time friend and colleague, H. Bernard Bechtel, M.D.

Sherman was a staunch supporter of SSAR and joined the society in the early 1960s when it was called The Ohio Herpetological Society. He and his wife, Madge Rutherford Minton, regularly attended OHS and SSAR meetings and were enthusiastic participants. It seems highly fitting, therefore, that Madge Minton and their three daughters (Brooks, April, and Holly) have donated Sherman's herpetological library to SSAR on the condition that it be auctioned and that the proceeds be used to continue Sherman's interests in society activities. Part of the library was auctioned at the society's joint meeting with The Herpetologists' League in Indianapolis in 2001. The remainder of the library, containing the more important and valuable books, will be auctioned this fall in an on-line auction conducted by SSAR's Publications Secretary, Breck Bartholomew.

If you wish to be notified about this auction, contact Mr. Bartholomew at ssar@herplit.com (phone/fax: 801-453-0489). The on-line auction will begin on or about October 2003. All proceeds will go to SSAR to establish The Sherman A. Minton, Jr., M.D. Endowment, to support student attendance at annual meetings.

NEWSNOTES

Conant and Stebbins Honored by SWAN

The Southwestern Association of Naturalists (SWAN) bestowed to Roger Conant and Robert C. Stebbins its highest honor, the W. Frank Blair Eminent Naturalist Award at the organization's Spring 2003 meeting. This award is named for William Franklin Blair (1912–1984), a long-time faculty member at the University of Texas. The Blair award recognizes excellence in a lifetime of commitment to outstanding study or conservation of the flora or fauna of the Southwest. This was the first time two individuals were selected. Other herpetologists previously honored include Charles C. Carpenter (1986), James R. Dixon (1987), Henry S. Fitch (1991), and Hobart M. Smith (2001). The Southwestern Association of Naturalists was founded in May 1953 to promote the field study of plants and animals (living and fossil) in the southwestern United States, Mexico, and Central America and to aid in the scientific activities of its members. The Association holds an annual meeting and publishes *The Southwestern Naturalist*. Membership is open to all persons interested in natural history. For more information consult the SWAN website at: http://www.biosurvey.ou.edu/swan.

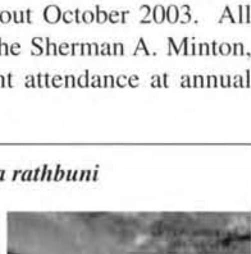
MEETINGS

Meetings Calendar

26–31 May 2004—47th Annual Meeting, Society for the Study of Amphibians and Reptiles, together with The Herpetologists' League and the American Society of Ichthyologists and Herpetologists. University of Oklahoma, Norman.

15–20 November 2004—VI Symposium of Zoology, Havana,

About Our Cover: *Eurycea rathbuni*



Among the least understood amphibians are those species exploiting groundwater or other subterranean environments. Obligate subterranean caudates (or "OSCs") are salamander species whose adults do not occur above ground. Between Europe and the United States, there exist at least 11 OSCs that display some degree of associated morphology that can include reduction or complete loss of pigment, reduction or complete loss of a visual system, hyper development of the lateral line system, limb attenuation and elongation, broadening and flattening of the head, an increased number of teeth compared to above ground relatives, and a shift toward paedomorphosis (Brandon 1971. National Speleological Society Bulletin 33[1]:1–21). Among OSCs, the move toward a paedomorphic condition is important. All but three or four OSC species are aquifer dwellers, and presumably have little or no terrestrial habitat available for occupancy.

The Cretaceous limestone uplifts of the Edwards Plateau of Texas are peppered with springs and caves. Many of the subterranean aquatic systems function as ecological islands because of their isolation, and consequently harbor endemic life forms (Chippindale et al. 2000. Herpetological Monographs 14:1–80). Among the regional endemics is the Texas Blind Salamander, *Eurycea rathbuni*, restricted to a small region of the Balcones Escarpment near San Marcos. More alien than salamander-like, these creatures captured the attention of the scientific community after the first individuals were discovered over 100 years ago. The specimens were belched from the mouth of a well that had been bored 58 m into the earth to tap water from an aquifer below (Stejneger 1896. Proceedings of the United States National Museum XVIII[1088]:619–621). Studying aquifer ecosystems is a daunting task and little is known of the life history of these ghostly amphibians. Texas Blind Salamanders are endangered as a result of groundwater overpumping. Conservation measures include captive propagation as well as efforts to protect their habitat from further water diversions.

Danté Fenolio photographed the cover subject at a U.S. Fish & Wildlife Service captive propagation facility. He used a Minolta 9xi, Minolta 100mm macro lens, Minolta dual flash unit, and Fuji Velvia film to record this image. Fenolio is a graduate student at the University of Oklahoma studying population dynamics and trophic interactions in another subterranean caudate, *Typhlotriton spelaeus*. He uses acrylic elastomer to mark and subsequently identify individuals. Gathering images of much of the Ozark Plateau's subterranean wildlife, Fenolio is collaborating with G. O. Graening of the Subterranean Biodiversity Project to produce a book on the subject.

Editor's note.—Special thanks to Ron Bonett for reviewing a draft of this text.

SSAR Grants-in-Herpetology 2004

Guidelines for Proposals

Proposals are now being accepted for the 2004 SSAR Grants-in Herpetology Program. This program is intended to provide financial support for deserving individuals or organizations involved in herpetological research, education, or conservation. Grant proposals will be considered in the following categories:

CONSERVATION OF AMPHIBIANS AND/OR REPTILES. Proposals should address research (particularly conservation biology) on species endangered or threatened at the state, national, or international level, or address research on potentially threatened habitats or species, or on introduced injurious species. Proposals must be accompanied by a letter of support from another member of the SSAR or a student's major advisor or committee chairperson.

FIELD RESEARCH. Proposals may address needs for field station fees or equipment and materials in field oriented projects, or the field work portions of broader studies. This might include in-situ behavioral studies, ecological, life history, or sexual selection studies. Survey work by individuals or regional societies may be submitted here or in TRAVEL below depending on how the funds are to be used. Proposals must be from individuals only and be accompanied by a letter of support from another member of the SSAR, the president of the sponsoring regional society (if applicable), or a student's major advisor or committee chairperson.

LABORATORY RESEARCH. Proposals may address needs for equipment or materials in laboratory projects or laboratory portions of broader projects. This might include studies in behavior, biochemistry, molecular biology, biomechanics, or physiology. Proposals must be from individuals only and be accompanied by a letter of support from another member of the SSAR or a student's major advisor or committee chairperson.

HERPETOLOGICAL EDUCATION. Proposals may address an educational project or start up support for an educational program in a zoo, museum, park, nature center, regional herpetological society, etc. The project must focus on a herpetological topic. Proposals must be from individuals only and be accompanied by a letter of support from the herpetological curator, the director of the facility, or the regional society president.

TRAVEL. Proposals may address support for travel to field study sites near or far, or to utilize distant collections or facilities. If funding is sought to get from one place to another, proposals should be submitted in the TRAVEL category. Proposals normally submitted in the CONSERVATION or FIELD RESEARCH categories should be submitted here if travel funding is being sought. Proposals must be accompanied by a letter of support from another member of the SSAR or a student's major advisor or committee chairperson, or the regional society president.

INTERNATIONAL. Proposals may address needs in any of the above five categories. Applicants must be from, and currently enrolled in an educational institution in, a country where herpetological research has historically been underfunded, and where alternative sources of financial support are scarce or nonexistent.

BIBLIOGRAPHIC RESEARCH. This special category continues for 2004, thanks to a donation from Itzchak and Carolyn Gilboa. Proposals should address a major need to consult library or other information resources. The project must focus on a herpetological topic. Proposals from individuals only, accompanied by a letter of support from someone knowledgeable about the applicant and about the importance of the project.

In keeping with the Society's goal of encouraging participation by the broadest possible community, preference may be given to individuals who might not have access to other funding sources. All applicants must be students AND members of the SSAR with the exception that those applying for support of regional herpetological society projects or the International category need not be SSAR members. Membership dues must be paid (to SSAR Treasurer) no later than 31 December 2003 for proposals to be considered. Applicants are limited to submission of one proposal in one category per year. In June 1999, the SSAR Board decided that past award recipients are not eligible for additional GIH awards. Applicants must designate to which of the six categories their proposal is submitted (although the committee reserves the right to reassign proposals to categories). If proposals in any of the categories are not forthcoming, or judged not to be of sufficient quality, the funds in those categories may be transferred to other categories. Each proposal must include the following: **(A) TITLE PAGE** giving the title of the project, the name, mailing address, office and home telephone numbers and, if possible, fax number and e-mail address of the applicant. The title page should also include the following numerated items completed in this format in the bottom left corner of the Title Page:

1) Category:
2) Word count:
3) Student status (give school):
4) SSAR membership since:
5) SSAR budget portion:
6) a statement indicating that applicants "will comply with all applicable permit regulations, and adhere to all appropriate animal care guidelines in the course of conducting funded projects.";

(B) BACKGROUND AND OBJECTIVES of the proposed project. **(C) METHODS** of carrying out the project. **(D) COMPLETE PROJECT BUDGET** (regardless of whether the SSAR grant will entirely cover expenses). Include an explicit explanation of how an SSAR award of $500 would be applied toward the objectives of the project (here as well as on Title Page), and provide a listing of all current and pending support for the project. **(E) BRIEF RESUMÉ/CURRICULUM VITAE** of the applicant or project coordinator. **(F) LETTER OF SUPPORT.** The proposal must be typed, double spaced, and must not exceed 1200 words, excluding title page, literature cited, resumé, and budget.

All proposals must be submitted (post-marked or email date) no later than **31 December 2003** to be considered. Electronic submission in any format is strongly encouraged. Failure to meet these guidelines may result in elimination of a proposal from consideration. The awards will be announced on or around 1 April 2004. Successful applicants are encouraged to submit the results of their research for publication in the Journal of Herpetology or Herpetological Review, or to present their findings at the annual meeting of the SSAR. Submit proposals or questions regarding application procedures to: **Erik R. Wild, Chair, SSAR Grants-in-Herpetology, Department of Biology, University of Wisconsin-Stevens Point, Stevens Point, Wisconsin 54481-3897, USA. Tel. (715) 346-4269; Fax (715) 346-3624; email *ewild@uwsp.edu.***

Cuba. Information: Executive Secretary: Dr C. Daysi Rodríguez Batista (zoologia.ies@ama.cu) or www.geocities.com/zoologiacubana/simposio.

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **Eli Greenbaum** or **Omar Torres-Carvajal**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can now be found at: http://www.herplit.com/contents.

Escape Behavior of *Cnemidophorus murinus*

Little is known about the additive or interactive risks and costs associated with escape behavior; predictions of optimal escape theory suggest an interaction between risk and cost factors. The authors examined escape behavior in *Cnemidophorus murinus*, a teiid lizard that relies on speed to escape predators. Two experiments tested lizard reactions to human "predators" at differing speeds and approaches. Statistical analyses included factorial ANOVA and chi-square tests. Rapid and direct approaches by humans elicited the strongest escape behaviors by lizards. When food was present, flight initiation distance was significantly shorter than trials with no food. These results suggest that one risk factor can affect the response to another, but the risks might not be additive as suggested by previous studies. The data do not fully support predictions of the optimal escape theory.

Cooper, Jr., W. E., V. Pérez-Mellado, T. Baird, T. A. Baird, J. P. Caldwell, and L. J. Vitt. 2003. Effects of risk, cost, and their interaction on optimal escape by nonrefuging Bonaire whiptail lizards, *Cnemidophorus murinus*. Behavioral Ecology 14:288–293.

Evolution of Venom-Injection Morphology in Snakes

Snakes possess a panoply of sophisticated and efficient venom-delivery systems (VDS) that include venom, venom glands and associated muscles, fangs, and maxillary dentition. There are approximately 450 venomous species in the Colubroidea clade, and previous workers have hypothesized that VDS evolved multiple times in this group. To test this hypothesis, Jackson used two previously published snake phylogenies to track several VDS characters; information about VDS characters was obtained from the literature. The most parsimonious interpretation of the results suggests: (1) Duvernoy's gland evolved once at the base of the colubroid tree; (2) viperids, atractaspidids, and elapids independently evolved venom glands (from Duvernoy's gland) and compressor glandulae muscles; (3) the pterygoideus was anteriorly attached in basal colubroids and moved to a posterior attachment in Elapidae and some aparallactines; (4) tubular fangs probably evolved independently several times in Colubridae, whereas grooved fangs might have been acquired and lost several times.

Population Trends and Extinction of Amphibians

Population declines are closely associated with extinction risk, but many *r*-selected amphibian species show fluctuating population sizes that are difficult to link to overall declines. Green examined 617 time series of population census data from 89 amphibian species to address the relative degree of variance in population sizes and how variation in demographic characteristics and habitat requirements affect extinction risk. In general, higher levels of population variance were observed in large stream-breeding and pond-breeding species relative to terrestrial direct-developing or small stream-breeding species. The population crash rates were 3.1% and 2.2% for pond-breeding frogs and pond-breeding salamanders, respectively; crash rates were negligible for stream-breeding and terrestrial direct-developing species. High population variance was associated with the smallest populations but not with life-history complexity. Species with high levels of population fluctuation and local extinctions might be susceptible to habitat fragmentation.

Green, D. M. 2003. The ecology of extinction: population fluctuation and decline in amphibians. Biological Conservation 111:331–343.

Effects of Temperature on Locomotor Performance of a Salamander

Studies of locomotor performance in anurans have suggested that amphibians are more likely to possess thermal insensitivity if they live in environments with large temperature fluctuations. The three-lined salamander *(Eurycea guttolineata)* is a model organism to study this phenomenon because females inhabit aquatic habitats (low temperature fluctuations) during the breeding season and terrestrial habitats (high temperature fluctuations) at other times of the year. Marvin measured aquatic and terrestrial locomotor performance of salamanders in a racetrack. In general, salamanders moved faster at higher temperatures; stride length was significantly greater at lower temperatures. These results do not support the hypothesis that terrestrial taxa are more thermally insensitive during locomotion. However, the results demonstrate that metamorphosed amphibians are capable of thermal acclimation

during locomotion.

Species Delimitations in *Liolaemus*

The process of species delimitation is fraught with controversy and numerous methodologies have been proposed in the literature. The authors agree with previous contentions that the strongest support for species delimitations should be based on concordance of independent data sets. To address this issue in the lizard genus *Liolaemus*, the authors examined mtDNA (cyt *b*, ND4, 12S) sequences from 198 samples of the *L. elongatus-kriegi* complex. The authors combined phylogenetic analyses (Bayesian, maximum parsimony, and maximum likelihood) with haplotype networks constructed from nested-clade analyses of complete cyt *b* sequences. All methods recovered three clades that the authors call the *elongatus, kriegi*, and *petrophilus* groups. Species boundaries of numerous samples are discussed; the analyses indicated that numbers of species in the *L. elongatus-kriegi* complex might be doubled. Numerous factors, including sample size and gene flow, might have affected tree topologies. The combined analyses proposed in this paper will allow future researchers to: (1) use large data sets to examine species boundary questions; (2) decrease costs associated with sequencing; and (3) improve statistical rigor.

MORANDO, M., L. J. AVILA, AND J. W. SITES, JR. 2003. Sampling strategies for delimiting species: genes, individuals, and populations in the *Liolaemus elongatus-kriegi* complex (Squamata: Liolaemidae) in Andean-Patagonian South America. Systematic Biology 52:159–185.

Larval Characters and Systematics of Frogs

Despite the steadily increasing number of described species, efforts to resolve anuran phylogenetic relationships are hampered by poor systematic exploration of taxa and their characters. The author examined 156 characters (mostly by personal examination) from 81 ingroup anuran taxa and four salamander outgroup taxa for the purposes of a phylogenetic analysis of major groups of frogs. Analysis of informative characters were conducted with PAUP*, MacClade 4, NONA 2.0, and TreeRot 2.0. Three search strategies (ratchet PAUP, ratchet NONA, and heuristic PAUP) yielded identical strict consensus topologies. *Ascaphus truei* was identified as the sister taxon to all other frogs. The monophyly and relationships of numerous anuran groups are discussed. Homoplasy was common in the data set, but not restricted to specific organ systems. Well-supported clades included Bufonidae, Ceratophryinae, Dendrobatidae, Microhylidae and Scoptanura, Pipoidea, Pipidae, and Phyllomedusinae. This study confirms the importance of larval characters in phylogenetic reconstruction and evolutionary history of frogs.

Physiological Energy Expenditure of *Bufo marinus*

Specific dynamic action (SDA) is the total amount of energy used for ingestion, digestion, absorption, and assimilation of food. The authors examined SDA in the toad *Bufo marinus* with four meal sizes, four natural diets, and four temperature regimes. Fifty-five *B. marinus* were collected and housed in plastic storage boxes for experiments; some individuals of *B. alvarius, B. boreas, B. terrestris*, and *B. woodhouseii* were tested as well. Gas exchange was measured with closed-system respirometry. Meals of earthworms, superworms, crickets, and juvenile rats weighing 5%, 10%, 15%, or 20% of toad body mass were offered to *B. marinus* at four temperatures (20°, 25°, 30°, or 35°C). Statistical analyses included ANOVA, ANCOVA, correlations, and regressions. Peak and scope of VO_2, and SDA increased with larger meal sizes. Prey types with chitonous exoskeletons required a higher level of SDA for digestion. Each 5°C increase in body temperature (beyond 20°C) decreased the duration of the postprandial metabolic response by two days, but SDA was not significantly changed by temperature. When compared to other taxa, it is clear that the factorial scope of elevated metabolism (peak VO_2) increased with body size.

SECOR, S. M., A. C. FAULKNER. 2002. Effects of meal size, meal type, body temperature, and body size on the specific dynamic action of the marine toad, *Bufo marinus*. Physiological and Biochemical Zoology 75:557–571.

Speciation and Biogeography of the Lizard Genus *Proctoporus*

Based on geological evidence of a south-to-north progression of uplift of the Andes mountains, it is likely that colonization and subsequent allopatric speciation of high-elevation taxa also occurred in a south-to-north direction. Doan tested this hypothesis by conducting a phylogenetic analysis on all species of montane *Proctoporus*. Sixty characters of external morphology were collected from 28 species of *Proctoporus* and three outgroup taxa in the genera *Pholidobolus, Opipeuter*, and *Euspondylus*. Most of the characters were polymorphic; the Generalized Frequency Coding method was used to code these characters. Maximum parsimony analyses were executed with PAUP* version 4.0b10. Results support the monophyly of *Proctoporus;* relationships within

the genus are discussed. Based on this analysis, it appears that the genus *Proctoporus* originated in the central Andes. The consensus tree does not support a pattern of south-to-north speciation at finely scaled levels, but the overall branching order of the phylogenies supports the south-to-north hypothesis.

DOAN, T. M. 2003. A south-to-north biogeographic hypothesis for Andean speciation: evidence from the lizard genus *Proctoporus* (Reptilia, Gymnopthalmidae). Journal of Biogeography 30:361–374.

Systematics of Emydine Turtles

Plastral-shell kinesis is considered to be an anti-predator defense; this mechanism is restricted to emydine turtles, which include the genera *Clemmys, Emydoidea, Emys,* and *Terrapene.* To examine the monophyly of the subfamily Emydinae and track the evolution of plastral kinesis, the authors conducted a phylogenetic analysis (cyt *b*, ND4, and adjacent tRNA genes) of all emydine and two deirochelyine taxa. Maximum parsimony (MP) and maximum likelihood (ML) were conducted in PAUP*. A PH test allowed the cyt *b* and ND4 datasets to be combined. A single most parsimonious tree was obtained for both the MP and ML analyses; these trees differed in the placement of a single taxon, *Clemmys marmorata.* Results supported a monophyletic *Terrapene* and paraphyletic *Clemmys.* The authors recommend restricting the name *Clemmys* to a single species (*C. guttata*) and expanding the genus *Emys* to include *E. marmorata, E. orbicularis,* and *E. blandingii.* Moreover, *Calemys* is resurrected for *C. muhlenbergii* and *C. insculpta;* the genus *Actinemys* and *Emydoidea* should be used as subgenera for lineages within *Emys.* Shell kinesis appears to have evolved twice—once in *Terrapene* and once in *Emys.* (See Crother et al. [this issue p. 196] for a discussion of the recommended changes suggested in this summary.)

Bothriechis schlegelii (Schlegel's Pitviper). Costa Rica. Illustration by Julian C. Lee.

ZOO VIEW

Two prominent zoo curators have recently retired from the zoo field: René E. Honegger and R. Howard Hunt. Both have been valued colleagues and friends for over thirty years and their accomplishments and commitment to our profession deserve mention.

René Honegger was the Curator of Herpetology at the Zürich Zoo in Switzerland between 1960 and 1999, and in charge of the Exotarium from 1972. He has been a major player in zoo biology by developing many innovations in terrarium displays, captive husbandry and management, and zoo philosophy. René compiled the first Red Data Book on amphibians and reptiles and has been involved in national and international conservation issues. Honegger has focused on protecting endangered herps in Europe. His career serves to demonstrate that a zoo worker can be an effective conservationist and he has published widely on conservation topics. He retired in October 1999.

When I entered the zoo field as a keeper at Zoo Atlanta in 1966, John (Steve) Dobbs was the Curator and his assistant was R. Howard Hunt. I only stayed in Atlanta briefly because the opening of the new reptile building was to be delayed; the exhibits had been built with a toxic bonding agent that proved deleterious to reptiles. This unfortunate design flaw caused a protracted legal struggle between the architect and zoo officials. When the building finally opened several years after my departure, Hunt specialized in crocodilians, making use of the several large solariums with living plants available for large reptiles. Some exceedingly large Morelet's crocodiles lived in the enclosure and later bred regularly. When Dobbs was elevated to Zoo Director, Hunt became the Curator.

Hunt has a rapport with crocodilians that I have rarely seen and he taught me a great deal about them. Howard asked me once if crocodiles have acute vision. When I hesitated, he threw some mealworms to a large male estuarine crocodile which was resting in its pool. The animal quickly picked the insects off the surface of the water and swallowed them.

I was responsible for cleaning the many crocodilian pools and was a bit apprehensive to be next to so many large and potentially dangerous reptiles. Thus I was surprised one day to discover Howard lying motionless on his stomach amidst a number of larger specimens. I yelled to see if he was OK and he calmly rose and said that he was fine. When, naturally, I asked what he was doing, he said he just wanted to see what it was like to be a crocodile!

Although retired, Howard continues his long-term study of American alligators in the Okefenokee Swamp. Many years ago, I asked how his study was progressing. Things were generally going well, he said, although donning a bear costume (usually reserved for parties) in order to test nesting female gators' responses to potential predators had, during the blazingly hot summer, nearly caused a major heat stroke.

Thomas Van Devender and his brother R. Wayne used to regularly visit with me at the Dallas Zoo when they were youngsters in the mid-1960s. Now, Wayne is a biology professor at Appalachian State University in North Carolina and Tom is a senior research scientist at the Arizona-Sonora Desert Museum in Tucson. For years, Tom has studied the environmental history and evolution of the Desert and has focused on the ecology and conservation of the

desert tortoise. In 2002, he edited a book called "The Sonoran Desert Tortoise: Natural History, Biology, and Conservation" (University of Arizona Press, Tucson) which is an important compendium of present knowledge about this endangered chelonian.

Increasingly, zoo workers are developing partnerships with a number of other zoos, governmental agencies, and conservation organizations. The paper below by Christina Castellano and her associates provides a nice model for these potentially productive interactions.

The Wildlife Conservation Society (WCS) and the National Park Service (NPS) have joined together under a cooperative agreement and in partnership to record the reptile and amphibian biodiversity on NPS lands. Launched in 1999, the project aims to inventory reptile and amphibian populations in more than 10 national parks, historic sites, national seashores, and national recreation areas in the northeastern United States.

Reptile and amphibian populations are in precipitous decline throughout the northeast. A combination of habitat loss and fragmentation, exotic plant and animal invaders, pollution, soaring predator levels, incidental take, and over-collection are to blame. For some amphibians and reptiles, America's parklands are their last retreat. In fact, some of the largest surviving woodlands and wetlands are preserved in America's parks. For that reason, NPS initiated the Inventory and Monitoring Program to establish a species database documenting the occurrence of vertebrates and vascular plants on parklands. The program compiles existing information from national databases and institutions, such as museums and universities, and combines it with data generated by targeted field investigations. To accomplish the program's goals, NPS is partnering with institutions and individuals that can provide the required assistance, manpower, and expertise for the mission at hand.

One of the NPS/WCS field crews conducting a snake survey using coverboard arrays at Acadia National Park.

Despite limited information, wildlife biologists recognized that NPS sites in the Northeast represented some of the most significant habitats remaining on the increasingly suburbanized landscape, and likely supported some of the more significant remnants of the region's herpetofauna. The cooperative agreement between WCS and NPS, drafted by Robert Cook (NPS) and John Behler (WCS), has strengthened the database and put the large-scale herpetological inventory in motion.

Parks inventoried since the program's inception include Acadia National Park in Maine, Gateway and Fire Island National Seashores in New York, Morristown, Sagamore Hill and Saratoga, Weir Farm, Saint-Gaudens, and Minute Man National Historic sites in New Jersey, New York, Connecticut, New Hampshire, and Massachusetts, respectively, and the Delaware Water Gap National Recreation Area on the Pennsylvania-New Jersey border. Each of these areas varies greatly in size and scope. Weir Farm in western Connecticut, roughly 24 hectares in size, provides an outdoor experience for a moderately populated residential community. Conversely, Delaware Water Gap National Recreation Area (DEWA) encompasses more than 60 km of the Delaware River and 28,000 hectares of land along its Pennsylvania and New Jersey shores. It is the largest recreational facility in the eastern United States and receives more than 5 million visitors annually.

NPS/WCS field teams have included nearly 30 biologists with a wide range of herpetological expertise. Additionally, student volunteers from Fordham, East Stroudsburg, and Hofstra universities and the University of Maine have participated in various aspects of the project including reptile and amphibian trapping, amphibian calling and egg mass count surveys, time constrained searches, cover board sampling, threatened and special concern species surveys and habitat assessment, and radio telemetry.

The herpetological diversity found at some of the study locations has provided additional opportunities to address more targeted questions. For example, the fens and seeps, cobble beaches, river islands, waterfalls, talus slopes, and shale cliffs that pervade the landscape at DEWA are home to nearly 50 species of reptiles and amphibians, some of which are recognized as *Endangered*, *Threatened*, *Rare*, or of *Special Concern* at the state or federal level. Some of DEWA's significant herpetofauna includes the longtail salamander (*Eurycea longicauda*), spring salamander (*Gyrinophilus porphyriticus*), northern cricket frog (*Acris gryllus*),

Graduate students from East Stroudsburg and Fordham universities recording shell measurements on a painted turtle at Delaware Water Gap National Recreation Area.

bog (*Glyptemys muhlenbergii*), wood (*Glyptemys insculpta*), and northern map (*Graptemys geographica*) turtles, eastern fence lizard (*Sceloporus undulatus*), and timber rattlesnake (*Crotalus horridus*). The information generated by the NPS/WCS teams will be used to plan infrastructure development and for designating wildlife sensitive areas.

NPS has a mandate to manage park resources in a manner that will leave them unimpaired for the enjoyment of future generations of park visitors. It recognizes that the fate of many of our greatest ecological and herpetological communities may rest with the conservation initiatives and wise management of the natural resources under its stewardship. Base-line inventories, with the generation of complete species lists and estimates of relative abundance, as well as the identification of key habitat features, are the necessary first steps in preserving our nation's herpetological resources. They provide the basic tools and grist to create long-term monitoring and resource protection programs to achieve these goals.

The DEWA field crew completing a northern fence lizard survey on the shale cliffs of the Pocono Plateau in eastern Pennsylvania.

The Importance of Reporting the Geodetic Datum with Geographic Coordinates

ERIC D. ROTH

e-mail: myuan@ou.edu

In natural history notes and other herpetological manuscripts it has become increasingly popular to report the geographic coordinates (e.g., latitude/longitude, UTM) of animal locations and study sites. Unfortunately, the geodetic datum on which these coordinates are based is rarely reported. The lack of datum information with geographic coordinates hinders the integration of location data from individual studies because the coordinate readings of a given geographic location can vary significantly with different datums. If biologists are to use published coordinates to accurately analyze the collection locations of museum specimens, produce range maps, plot population distributions, or examine other spatial patterns, it will be critical to have the datum associated with the reported geographic coordinates.

We argue that geographic coordinates for biological data should be reported with the referenced datum so that published location data can be integrated to provide a more precise geographic view of species distributions and natural history observations.

What is a Datum?

A geodetic datum (here after referred to as datum) is a model of the Earth for geodetic measurements and geo-references of locations (DeMers 2000; McDonnell and Kemp 1995). The datum defines the shape and size of the Earth and the origin and orientation of a coordinate system from which locations on the surface of the Earth can be referenced. There are hundreds of datums currently in use for geo-referencing locations (horizontal datums) and estimating elevation (vertical datums). Horizontal datums assume that the surface of the earth is smooth and can be mathematically approximated as an ellipsoid.

Why is Reporting the Datum Important?

To illustrate the importance of the datum, we have plotted a single geographic coordinate (25°42'14", -124°50'24") referenced from seven different datums (Fig. 1). This graphically demonstrates that identical geographic coordinates are not representative of the same location if they are based on different datums. To explain why these position shifts occur, one must consider how geographic coordinates are calculated. The definitions of latitude and longitude are based on the assumed ellipsoidal surface of the Earth (Featherstone and Vanicek 1999). Different ellipsoids relative to a

specific datum may result in different readings of latitude and longitude for a given geographic location. Therefore, coordinates from different datums are incompatible because coordinate readings are relative to the origin, shape, and size of the respective datum. Failure to transform coordinates to a single datum can cause coordinate shifts and result in measurement errors. For example, the North American datum of 1927 (NAD27) was the primary datum used in early 1:24000 topographic maps published by the United States Geological Survey (USGS). Later, the USGS adopted the NAD83 datum which is based on the geodetic reference system of 1980 (GRS80) ellipsoid. The change from NAD27 to NAD83 resulted in as much as 300-m shifts in identical locations on the ground (Clarke 2001).

Reporting the referenced datum allows researchers to standardize geographic coordinates. In most cases, the National Imagery and Mapping Agency (NIMA) has developed mathematical transformations of geographic coordinates among various datums (NIMA 1991), and many geographic information systems (GIS) have built-in functions for datum transformation. Enhanced software capabilities and other improvements in GIS technologies have increased the feasibility of integrative biological studies and the analysis of fine to broad-scale spatial patterns, but these capabilities require datum information along with the geographic coordinates. Without reporting the datum, the 1–15 m accuracy achieved by many handheld GPS receivers may be degraded to hundreds of meters. This potentially introduces substantial error as biologists attempt to compile spatial data and assess ecological relationships. For example, coordinate shifts may falsely place the reported location of a museum specimen in neighboring populations, communities, or habitats, thus limiting ecological interpretations.

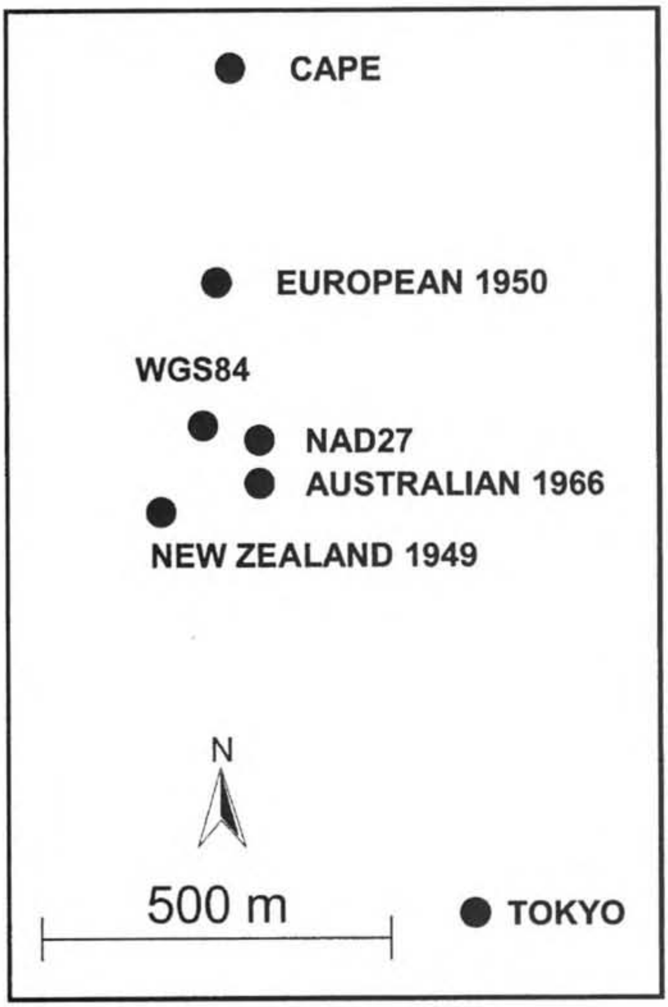

FIG. 1. The locations of a single geographic coordinate (25°42'14", -124°50'24") based on different datums are plotted. The datum on which these identical coordinates are based is listed next to each location.

Which is the Most Appropriate Datum?

As most GPS receivers can be set to the datum of choice, researchers are faced with the problem of choosing an appropriate datum for a desired task. To avoid problems with coordinate conversions, researchers may elect to choose a datum that matches other research materials, such as coordinates obtained from previous studies or chosen reference maps. Another factor to consider when choosing a datum is whether the datum coverage is local or global. A datum is defined by an ellipsoid and a coordinate origin. A local datum has a coordinate origin at a specific point on the Earth's surface (Featherstone and Vanicek 1999). For example, the NAD27 adopts the Clarke 1866 ellipsoid with the coordinate origin at Meades Ranch, Kansas (NIMA 1983). Local datums are commonly used to produce local and regional maps. An advantage of choosing a local datum may be that location errors are minimized near the referenced coordinate origin. However, spatial accuracy decreases as distances from the coordinate origin increase. Consequently, local datums may only be appropriate for specific regions. While choosing a datum may depend upon the availability of a local datum near the chosen study location, biologists may also want to consider the spatial scale of the investigation. Global datums, such as the world geodetic system of 1984 (WGS84), use a coordinate origin from the center of the Earth. Therefore, the spatial distortion from the reference ellipsoid is minimized globally. The WGS84 was developed by NIMA for global mapping production and is commonly used by global positioning systems (NIMA 1997). For these reasons, WGS84 is a frequently referenced global datum and may be appropriate for most biological studies.

Reporting the Datum and Other Spatial Information

When creating collection databases or reporting natural history observations, researchers should also consider the coordinate system being used and the other spatial information that may be required. For example, if a universal transverse mercator (UTM) coordinate system is chosen, then the UTM zone should also be reported with the datum. Similarly, a zone must also be reported when using the state plane coordinate system. The datum information, coordinate system, and zone (if applicable) can usually be obtained from the map or GPS receiver being used for geo-referencing. With the proliferation of spatial data, there is a growing need for biologists to familiarize themselves with these spatial concepts and report all information critical to the standardization of geographic coordinates.

Acknowledgments.—Thanks to Shawn Sartorius, Tania Roth, and Jens Vindum for comments on the manuscript.

Egyptian Tortoise Conservation: A Response to Perälä

SHERIF BAHA EL DIN
ESTHER WENMAN
GIAN LORENZO
OMAR ATTUM
and
MINDY BAHA EL DIN
Participants in the TortoiseCare Program
C/o 3 Abd Alla El Katib Street, Dokki, Cairo, Egypt
e-mail (SBD): baha@internetegypt.com

We would like to make clarifications regarding inaccurate statements made in Perälä (2001) concerning *Testudo kleinmanni* conservation efforts in Egypt, particularly the "introduction" of confiscated Libyan animals into Sinai.

After the confiscation of some 300 animals of Libyan origin from the pet trade by Egyptian authorities in 1997, we were given the task of repatriating these animals to their "natural habitats." Options for doing this west of the Nile are, unfortunately, very limited. Given the reasonable management of Zaranik Protected Area in North Sinai, and working under the assumption that local tortoise populations had been completely extirpated, we decided to explore the possible release of a pilot group of 50 animals to this region. Being aware of potential biogeographical consequences of the introduction of western animals to areas east of the Nile, the animals were transferred into controlled environments, where the risk of release into the wider landscape was minimal. After a detailed health screening (D'Alterio et al. 1999), 40 animals were placed in a double-fenced enclosure, and 10 animals were radio-tagged and placed on a small offshore island.

In the spring of 2000, as a consequence of our efforts to raise tortoise conservation awareness in the local community, a small population of native tortoises was discovered in Zaranik Protected Area (31°05'N, 33°28'E; Baha El Din and Attum 2000), which is not near the Israeli border, as suggested by Perälä (2001). As a consequence we decided to transfer all the Libyan animals to another enclosure between Cairo and Alexandria, and to shift the emphasis in Zaranik to the *in situ* conservation of the local population.

To date we have succeeded in finding a population of over 60 wild animals in Zaranik Protected Area. This population is closely monitored by community guards, who track the animals on a regular basis. In addition, 16 animals have been radio-tagged to facilitate the collection of further ecological and behavioral data, which would aid in the conservation of this population. Moreover, we have been actively seeking the cooperation of the local Bedouin community in tortoise conservation through personal communication and the development of a very successful handicraft program. Other activities include public awareness, maintenance of confiscated animals, health profiling of the species, and lobbying government authorities. We are also in contact with Libyan colleagues and authorities to ban the illegal collection and trade in these animals.

Perälä's comparison of our efforts in Zaranik with a case concerning *Gopherus agassizii* in the USA described by Jacobson et al. (1995) is inappropriate, as the two situations are not similar at all. There was known to be a large native population of *G. agassizii*, into which over 800 *G. agassizii* were relocated. In our situation, no wild populations were known, and "introduced" animals were kept isolated and under control. Perälä's statement that our efforts are a "major and immediate threat" to the survival of the Sinai populations of *Testudo kleinmanni* reflect a real lack of understanding of the scale, scope, and imminence of the threat from habitat destruction and collection for the pet trade these creatures face throughout their range.

This publication serves as an update for the most recent list of scientific and standard English names of North American amphibians and reptiles north of Mexico (Crother et al. 2000. SSAR Herpetol. Circ. 29). The list below should to be used in conjunction with the previous work (*op. cit.*). This update includes new taxa described since the previous publication and any taxonomic changes that have led to name changes, both English and scientific.

A number of changes herein concern date of publication of the original species description. In the course of other work, one of us (McDiarmid) reviewed the dates of publication for species of amphibians and reptiles. A primary source was *An Index to the Scientific Contents of the Journal and Proceedings of The Academy of Natural Sciences of Philadelphia*, published in 1913, pages vii–xiv, in Commemoration of the Centenary of the Academy, March 21, 1912. Data in the publication were drawn primarily from a file of 'receipt acknowledgments' received by the Academy from libraries to whom the *Journal* and *Proceedings* were sent. While useful in establishing a documented earliest date other than that printed on the volume, these acknowledgments likely were subject to the schedules of the various responding librarians and therefore not always helpful when the year of response was different from the stated date of publication. Another potential source of data are accessions files of the various libraries receiving the publications and initial contact with the library of the American Philosophical Society clarified the date of publication for volume 8 [1856] of the *Proceedings*. We hope that further research along these lines will provide definitive dates for most of these volumes and expect that additional updates will be needed in the future.

The task of compiling the kind of information that goes into these publications is not trivial. We encourage colleagues to please send reprints concerning any taxonomic changes or decisions relevant to this list. Receiving such reprints will help ensure these names lists are as complete as possible.

Anura — FROGS

Compiled by Darrel Frost

Ascaphus Stejneger, 1899—TAILED FROGS
Ritland et al. (2000, Can. J. Zool. 78: 1749–1758), using randomly amplified polymorphic DNA (RAPD), found large genetic distances between isolated coastal and Rocky Mountain populations of *Ascaphus* in British Columbia, as well as genetic differentiation between north and south coastal populations. Subsequently, Nielson et al. (2001, Evolution, 55: 147–160) reported on mtDNA variation among the isolated populations in the Pacific Northwest, concluding that former *Ascaphus truei* is composed of at least two species, and recognized these as *Ascaphus truei* and *Ascaphus montanus*.

A. montanus Mittleman and Myers, 1949—Rocky Mountain Tailed Frog

A. truei Stejneger, 1899—Coastal Tailed Frog

See Metter (1968, Cat. Am. Amph. Rept. 69) for review (as including *Ascaphus montanus*).

Bufo alvarius Girard, 1859—Sonoran Desert Toad

B. americanus Holbrook, 1836—American Toad

B. a. charlesmithi Bragg, 1954—Dwarf American Toad

Masta et al. (2002, Mol. Phylogenet. Evol. 24: 302–314) found that *Bufo americanus charlesmithi* was concordant with a distinctive mtDNA clade in their analysis, suggesting that it might be an independent lineage.

B. boreas Baird and Girard, 1852—Western Toad

See Schuierer (1963, Herpetologica 18: 262–267). Two (sometimes three, see *Bufo nelsoni*) nominal subspecies are generally recognized, although the geographic variation within *Bufo boreas* is poorly studied and may mask a number of cryptic species.

B. b. boreas Baird and Girard, 1852—Boreal Toad

B. b. halophilus Baird and Girard, 1853—California Toad

B. fowleri Hinckley, 1882—Fowler's Toad

Masta et al. (2002, Mol. Phylogenet. Evol. 24: 302–314), on the basis of molecular evidence suggested that *Bufo fowleri* is a distinct species composed of three molecularly distinctive populations, which require additional study as to their taxonomic status.

B. nebulifer Girard, 1843—Gulf Coast Toad

Mendelson (1994, Occas. Pap. Mus. Nat. Hist. Univ. Kansas 166: 1–21; 1997, Herpetologica 53: 14–30) showed that a number of cryptic species were concealed under the name *Bufo valliceps* and subsequently (Mulcahy and Mendelson, 2000, Mol. Phylogenet. Evol. 17: 173) recognized that nominal *Bufo valliceps* was composed of a northern species (*Bufo nebulifer*) in the USA south to central Veracruz, Mexico, and another (*Bufo valliceps*) from central Veracruz, Mexico, to Costa Rica. Although the scientific name of the Gulf Coast Toad has changed, and the likelihood remains that *Bufo valliceps* (sensu stricto) may still hold some surprises, it is unlikely that *Bufo nebulifer* represents more than one lineage.

B. nelsoni Stejneger, 1893—Amargosa Toad
Considered by some to be an allopatric subspecies of *Bufo boreas*. Stebbins (1985, Field Guide W. Rept. Amph., Ed. 2: 70) recognized this allopatric and morphologically distinct population as a distinct species. Altig et al. (1998, Contemp. Herpetol. Inform. Ser. 2: 7) noted its allopatry from *Bufo boreas* as well as fixed differences between larvae. Morphological distinctiveness of the two forms is not controversial.

B. woodhousii Girard, 1854—Woodhouse's Toad
See comments under *Bufo fowleri* in the previous list. The unjustified emendation of the specific epithet to *woodhousei* has been used widely. The status of taxa recognized by Sanders (1987, Evol. Hybrid. Spec. N. Am. Indig. Bufonids: 1–110), has not been evaluated closely by any author, although they have neither enjoyed any recognition. Subspecies in this taxon are controversial, with two (*B. w. australis* and *B. w. woodhousii*) frequently recognized. A third nominal subspecies, *B. w. velatus* Bragg and Sanders, 1951 (East Texas Toad) has been suggested (Sullivan et al., 1996, Copeia 1996: 274–280), to represent part of a zone of hybridization between *Bufo fowleri* and *Bufo woodhousii* and so should not be recognized as a taxon until this issue is resolved. Detailed study of calls and molecules will likely prove fruitful within this widely distributed species. Masta et al. (2002, Mol. Phylogenet. Evol. 24: 302–314) noted that within *Bufo woodhousii* two distinct mtDNA clades exist which are largely concordant with the nominal subspecies *Bufo woodhousii woodhousii* and *Bufo woodhousii australis*, so additional work is warranted to determine the number of species under this name.

B. w. australis Shannon and Lowe, 1955—Southwestern Woodhouse's Toad

B. w. woodhousii Girard, 1854—Rocky Mountain Toad

Gastrophryne olivacea (Hallowell, 1856)—Great Plains Narrow-mouthed Toad

Hyla gratiosa LeConte, 1856—Barking Treefrog

H. wrightorum Taylor, 1939 "1938"—Mountain Treefrog
Until recently (Duellman, 2001, Hylid Frogs Middle Am., Ed. 2: 983–98) considered a synonym of *H. eximia*, in southern Mexico. Nevertheless, the evidence for considering the Mountain Treefrog as indistinguishable from its Mexican relative was always weak and never consistent with call structure. The status of populations of this species from Mexico (south to, but not including, the Mexico City region) is unknown.

Leptodactylus fragilis (Brocchi, 1877)—Mexican White-lipped Frog
No report of geographic variation. See Heyer (2002, Proc. Biol. Soc. Washington 115: 321–322) for summary of nomenclatural confusion regarding the name of this frog, formerly called *Leptodactylus labialis*.

Pseudacris regilla (Baird and Girard, 1852)—Pacific Treefrog
Transferred to *Pseudacris* by Hedges (1986, Syst. Zool. 35: 11) but was disputed by Cocroft (1994, Herpetologica 50: 420–437), although Silva (1997, J. Herpetol. 31: 609–613) provided additional evidence and discussion for placing this species within *Pseudacris*. See Jameson, Mackey, and Richmond (1966, Proc. California Acad. Sci. 33: 551–620) and Duellman (1970, Monogr. Mus. Nat. Hist. Univ. Kansas 1: 484–493). Several nominal subspecies named, though infrequently used in the literature. Whether these represent sibling species or arbitrarily delimited components of geographic variation is unknown. Further investigation is warranted. Highton (2000, Biol. Plethodontid Salamanders: 234) discussed the previously published allozyme evidence (including that of Case, Haneline, and Smith, 1975, Syst. Zool. 24: 281–295) and suggested that what genetic data as exist for *Pseudacris regilla* are not consistent with it being a single species.

P. streckeri A. A. Wright and A. H. Wright, 1933—Strecker's Chorus Frog

P. s. illinoensis Smith, 1951—Illinois Chorus Frog
Considered a distinct species, *Pseudacris illinoensis*, by Collins (1997, SSAR Herpetol. Circ. 25) without discussion.

Rana berlandieri Baird, 1859—Rio Grande Leopard Frog

R. capito LeConte, 1855—Gopher Frog
Rana capito is considered by some to be part of *R. areolata* (but see Case, 1978, Syst. Zool. 27: 299–311, who considered it distinct). Recognized as distinct from *Rana areolata* by Young and Crother (2001, Copeia 2001: 382–388), who also sugggested that the nominal subspecies are arbitrary units.

R. sevosa Goin and Netting, 1940—Dusky Gopher Frog
Reviewed (as *Rana areolata sevosa*) by Altig and Lohoefener (1983, Cat. Am. Amph. Rept. 324: 1–4). Recognized as distinct from *R. capito* and *R. areolata* by Young and Crother (2001, Copeia 2001: 382–388).

R. virgatipes Cope, 1891—Carpenter Frog
Data presented by Pytel (1986, Herpetologica 42: 273) suggest that careful evaluation for cryptic species is warranted.

Caudata — SALAMANDERS

Compiled by Richard Highton, Stephen G. Tilley (Chair), David B. Wake.

Ambystoma cingulatum Cope, 1868—Flatwoods Salamander

Batrachoseps gavilanensis Jockusch, Yanev, and Wake, 2001—Gabilan Mountains Slender Salamander.
See annotation under *B. pacificus*.

B. incognitus Jockusch, Yanev, and Wake, 2001—San Simeon Slender Salamander
See annotation under *B. pacificus*.

B. luciae Jockusch, Yanev, and Wake, 2001—Santa Lucia Mountains Slender Salamander
See annotation under *B. pacificus*.

B. minor Jockusch, Yanev, and Wake, 2001—Lesser Slender Salamander
See annotation under *B. pacificus*.

B. pacificus (Cope, 1865)—Channel Islands Slender Salamander
This formerly polytypic species now includes only populations found on the northern Channel Islands off the coast of southern California (Jockusch et al., 2001, Herpetol. Monogr. 15: 54–99; Jockusch and Wake, 2002, Biol. Jour. Linn. Soc. 76: 361–391). Former members of this taxon have been raised to species rank (*B. major, B. relictus*) or described as new species (*B. diabolicus, B. gavilanensis, B. incognitus, B. kawia, B. luciae, B. minor,* and *B. regius*).

B. robustus Wake, Yanev and Hansen, 2002—Kern Plateau Salamander

B. wrightorum (Bishop, 1937)—Oregon Slender Salamander
Applegarth (1994, Publ. USDI Bureau of Land Management, Eugene, Oregon) made the required emendation from *B. wrighti* to *B. wrightorum*. Petranka (1998, Salamanders of the United States and Canada, Smithsonian Institution Press) employed the original nomenclature.

Desmognathus brimleyorum Stejneger, 1895—Ouachita Dusky Salamander

D. conanti Rossman, 1958—Spotted Dusky Salamander
Elevated to species rank by Titus and Larson (1996, Syst. Biol. 45: 451–472). Treated as a subspecies of *D. fuscus* by Petranka (1998, Salamanders of the United States and Canada, Smithsonian Institution Press). Bonett (Copeia 2002: 344–355) showed that *D. conanti* and *D. fuscus* are

parapatric in Tennessee with only very limited hybridization, and that *D. conanti* consists of two clades of populations that may represent distinct species.

D. folkertsi Camp, Tilley, Austin, and Marshall, 2002—Dwarf Black-bellied Salamander

D. fuscus (Rafinesque, 1820)—Northern Dusky Salamander

Treated as a monotypic species by Titus and Larson (1996, Syst. Biol. 45: 451–472). Treated as a polytypic species consisting of *D. f. conanti*, *D. f. fuscus*, and *D. f. santeetlah* by Petranka (1998, Salamanders of the United States and Canada, Smithsonian Institution Press). Bonett (Copeia 2002: 344–355) showed that *D. conanti* and *D. fuscus* are parapatric in Tennessee with only very limited hybridization, and that *D. fuscus* consists of northern and southern clades of populations. He suggested that these may represent distinct species, although they appear to hybridize over a broad area in Virginia. Frost [2002. Amphibian Species of the World: an online reference. V2.21 (15 July 2002) http//research.amnh.org/herpetology/amphibia/index.html] applied the name *Desmognathus niger* Green to this taxon, noting that the name *Salamandra fusca* Green is a junior primary homonym of *Salamandra fusca* Laurenti (=*Salamandra atra*). However, contrary to the synonymies made by Gray, 1850, Cat. Spec. Amph. Coll. Brit. Mus., Batr. Grad.: 31, Hallowell, 1856, Proc. Acad. Nat. Sci. Philaelphia, 8: 7, and Dunn, 1926, Salamand. Fam. Plethodontidae: 81, Green's [1818, J. Acad. Nat. Sci. Philadelphia, (1)1: 357] descriptions of *Salamandra fusca* and two other taxa that might represent *Desmognathus fuscus* (*S. niger*, and *S. sinciput–albida*) are too vague to be associated unambiguously with any known species of salamander. *Triturus fuscus* was later described by Rafinesque (1820, Ann. Nat., Lexington, 1: 4), whose type description applies to this taxon less ambiguously than any of Green's. Rafinesque should therefore be considered the author of the name *Desmognathus fuscus*, while Green's *Salamandra fusca*, *S. niger*, and *S. sinciput–albida* should be regarded as *nomina dubia*.

D. wrighti King, 1936—Pygmy Salamander

Dicamptodon aterrimus (Cope, 1868)—Idaho Giant Salamander

Eurycea cirrigera (Green, 1830)—Southern Two-lined Salamander

See note for *E. wilderae*.

E. rathbuni (Stejneger, 1896)—Texas Blind Salamander

E. robusta (Longley, 1978)—Blanco Blind Salamander

E. wilderae Dunn, 1920—Blue Ridge Two-lined Salamander

Treated as a species by Jacobs (1987, Herpetologica 43: 423–446), Conant and Collins (1991, Reptiles and Amphibians of Eastern and Central North America, Houghton Mifflin Co.) and Collins (1997, SSAR Herpetol. Circ. 25) on the basis of its level of genetic differentiation from other members of the *E. bislineata* complex. Treated, together with *E. cirrigera*, as a subspecies of *E. bislineata* by Petranka (1998, Salamanders of the United States and Canada, Smithsonian Institution Press), but *E. wilderae* and *E. cirrigera* occur in sympatry (Camp et al., 2000, Copeia 2000: 572–578) and undergo very little gene exchange where they are parapatric (Kozak and Montanucci, 2001, Copeia 2001: 25–34).

Hemidactylium scutatum (Temminck and Schlegel in Von Siebold, 1838)—Four-toed Salamander

Hydromantes platycephalus (Camp, 1916)—Mount Lyell Salamander

Plethodon jordani Blatchley, 1901—Red-cheeked Salamander

The taxon was restricted to populations in the Great Smoky Mountains by Highton and Peabody (2000, pp. 31–94 in Bruce et al., The Biology of Plethodontid Salamanders, Kluwer Academic/Plenum Publishers), who also suggested the standard English name.

Typhlotriton Stejneger, 1892—Grotto Salamanders

T. spelaeus Stejneger, 1892—Grotto Salamander

Squamata — LIZARDS

Compiled by Kevin de Queiroz (Chair), Tod W. Reeder, Jack W. Sites, Jr.

"Ameiva" Meyer, 1795—AMEIVAS (Introduced)

Taxonomy for "*Ameiva*" follows Peters and Donoso-Barros (1970, Bull. United States Natl. Mus. 297: 1–293). Reeder et al. (2002, Am. Mus. Novit. 3365: 1–61) presented evidence that "*Ameiva*," as currently circumscribed, is not monophyletic, though they did not propose a taxonomic change to rectify this situation. We have placed the name "*Ameiva*" in quotation marks to indicate the non-monophyletic status of the taxon.

Anniella Gray, 1852—NORTH AMERICAN LEGLESS LIZARDS

Taxonomy for *Anniella* follows Hunt (1983, Copeia 1983: 79–89), with nomenclatural modifications (ICZN, 1993, Bull. Zool. Nomencl. 50: 186–187).

A. pulchra Gray, 1852—California Legless Lizard

Pearse and Pogson (2000, Evolution 54: 1041–1046) presented evidence that the melanistic form previously designated *Anniella pulchra nigra* is polyphyletic, its Monterey Bay and Morro Bay populations having been derived independently from the silvery form previously designated *A. p. pulchra*. Although Pearse and Pogson did not propose any taxonomic changes, their results indicate that the subspecies *A. p. pulchra* and *A. p. nigra* do not correspond with separated or partially separated lineages, and therefore we do not recognize subspecies within *A. pulchra*. The existence and extent of genetic continuity between melanistic and silvery populations, as well as between northern and southern haplotype clones, deserves further study.

Anolis cristatellus Duméril and Bibron, 1837—Crested Anole (Introduced)

A. c. cristatellus Duméril and Bibron, 1837—Puerto Rican Crested Anole (Introduced)

Anolis cristatellus cristatellus is established in Brevard and Dade Counties, Florida (Wilson and Porras, 1983, Univ. Kansas Mus. Nat. Hist. Spec. Publ. 9: 1–89 and references therein; Seigel et al., 1999, Herpetol. Rev. 30: 173). Subspecific identifications were not reported by Wilson and Porras (*op. cit.*) or Seigel et al. (*op. cit.*) but have been given for the Dade County specimens by Schwartz and Henderson (1988, Contrib. Biol. Geol. Milwaukee Publ. Mus. 74: 1–264; 1991, Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History, University of Florida Press).

Aspidoscelis Fitzinger, 1843—WHIPTAILS

Reeder et al. (2002, Am. Mus. Novit. 3365: 1–61) presented evidence that *Cnemidophorus*, as previously circumscribed, is not monophyletic, and they resurrected *Aspidoscelis* for the clade composed of the species native to North America. Not shown below but necessary to note is that all author names are in parentheses. This change affects the following species names:

C. arizonae becomes *A. arizonae*
C. burti becomes *A. burti* (*C. b. stictogrammus* becomes *A. b. stictogramma*)
C. dixoni becomes *A. dixoni*
C. exsanguis becomes *A. exsanguis*
C. flagellicaudus becomes *A. flagellicauda*
C. gularis becomes *A. gularis* (*C. g. gularis* becomes *A. g. gularis*)
C. gypsi becomes *A. gypsi*
C. hyperythrus becomes *A. hyperythra* (*C. h. beldingi* becomes *A. h. beldingi*)
C. inornatus becomes *A. inornata* (*C. i. heptagrammus* becomes *A. i. heptagramma*, *C. i. juniperus* becomes *A. i. junipera*, *C. i. llanuras* becomes *A. i. llanuras*)
C. laredoensis becomes *A. laredoensis*
C. marmoratus becomes *A. marmorata* (*C. m. marmoratus* becomes *A. m. marmorata*, *C. m. reticuloriens* becomes *A. m. reticuloriens*)
C. neomexicanus becomes *A. neomexicana*
C. neotesselatus becomes *A. neotesselata*

C. pai becomes *A. pai*

C. septemvittatus becomes *A. septemvittata* (*C. s. septemvittatus* becomes *A. s. septemvittata*)

C. sexlineatus becomes *A. sexlineata* (*C. s. sexlineatus* becomes *A. s. sexlineata*, *C. s. stephensae* becomes *A. s. stephensae*)

C. sonorae becomes *A. sonorae*

C. tesselatus becomes *A. tesselata*

C. tigris becomes *A. tigris* (*C. t. mundus* becomes *A. t. munda*[1], *C. t. punctilinealis* becomes *A. t. punctilinealis*, *C. t. septentrionalis* becomes *A. t. septentrionalis*, *C. t. stejnegeri* becomes *A. t. stejnegeri*, *C. t. tigris* becomes *A. t. tigris*)

C. uniparens becomes *A. uniparens*

C. velox becomes *A. velox*

C. xanthonotus becomes *A. xanthonota*

[1]Reeder et al. (*op. cit.*) mistakenly used the name *A. t. undulata* instead of the valid name *A. t. munda* (see Crother et al., 2000, SSAR Herpetol. Circ. 29).

A. laredoensis (McKinney, Kay and Anderson, 1973)—Laredo Striped Whiptail (unisexual)

Abuhteba et al. (2001, Copeia 2001: 262–266) interpreted histoincompatibility between the members of two pattern classes within *Aspidoscelis laredoensis* as evidence for separate hybrid origins of the corresponding clones. The authors noted that two of them are planning to restrict the name *A. laredoensis* to one of the clones and propose a new species name for the other.

A. marmorata Baird and Girard, 1852—Marbled Whiptail

Aspidoscelis marmorata (including *A. marmorata marmorata* and *A. m. reticuloriens* in the United States) was treated as a species by Hendricks and Dixon (1986, Texas J. Sci. 38: 327–402) but as a subspecies of *A. tigris* by Maslin and Secoy (1986, Contrib. Zool. Univ. Colorado Mus. 1: 1–60) and Wright (1993, Pp. 27–81 *in* Biology of Whiptail Lizards [Genus *Cnemidophorus*], J. W. Wright and L. J. Vitt [eds.], Oklahoma Mus. Nat. Hist.). Dessauer and Cole (1991, Copeia 1991: 622–637; see also Dessauer et al., 2000, Bull. Am. Mus. Nat. Hist. 246: 1–148) presented evidence of both differentiation and interbreeding between *marmorata* and *tigris* along a transect near the southern part of the border between Arizona and New Mexico, including a narrow (3 km) hybrid zone in which hybrid indices based on color patterns and allele frequencies changed abruptly in concordant step clines. Although those authors interpreted their data as reflecting incomplete speciation between the two forms (i.e., a single species), the same data can be interpreted alternatively as reflecting largely separate gene pools (i.e., two species). Following the terminology of de Queiroz (1998, pp. 57–75 *in* Endless Forms: Species and Speciation, D. J. Howard and S. H. Berlocher [eds.], Oxford University Press), they are here considered incompletely separated species.

"*Cnemidophorus*" Wagler, 1830—SOUTH AMERICAN WHIPTAILS

Taxonomy for "*Cnemidophorus*" follows Peters and Donoso-Barros (1970, Bull. United States Natl. Mus. 297(Part II): 1–293). Reeder et al. (2002, Am. Mus. Novit. 3365: 1–61) presented evidence that *Cnemidophorus*, even after the removal of *Aspidoscelis*, is not monophyletic, though they did not propose a taxonomic change to rectify this situation. We have placed the name "*Cnemidophorus*" in quotation marks to indicate the non-monophyletic status of the taxon.

Cosymbotus platyurus (Schneider, 1792)—Flat-tailed House Gecko (Introduced)

Cosymbotus platyurus is established in Alachua and Pinellas Counties Florida (Meshaka and Lewis, 1994, Herpetol. Rev. 25: 127; Hauge and Butterfield, 2000, Herpetol. Rev. 31: 52).

Crotaphytus vestigium Smith and Tanner, 1972—Baja California Collared Lizard

McGuire (1996, Bull. Carnegie Mus. Nat. Hist. 32: 1–143) noted that the name *Crotaphytus vestigium* Smith and Tanner is a junior synonym of *C. fasciatus* Mocquard. Nevertheless, he used the junior synonym as the valid name for the taxon because the senior synonym had not been so used during the last 50 years, while the junior synonym had been used repeatedly. McGuire also noted that *C. fasciatus* Mocquard is a junior (primary) homonym of *C. fasciatus* Hallowell (which is itself a junior synonym of *Gambelia wislizenii*) and that Mocquard, apparently aware of the problem, had provided the new replacement name (nomen novum) *C. fasciolatus*. Because the junior primary homonym *C. fasciatus* Mocquard is invalid (ICZN, 1999: Article 57.2), the correct name for this taxon is *C. fasciolatus*; however, for the reasons noted above, McGuire (2000, Bull. Zool. Nomencl. 57: 158–161) has proposed that *C. fasciolatus* be suppressed. Until the International Commission on Zoological Nomenclature rules on this proposal, we have followed the Zoological Code (ICZN, 1999: Article 82.1) by maintaining the name in most common current use.

Eumeces "gilberti" Van Denburgh, 1896—Gilbert's Skink

Richmond and Reeder (2002, Evolution 56: 1498–1513) presented evidence that populations previously referred to *Eumeces gilberti* represent three lineages that separately evolved large body size and the loss of stripes in late ontogenetic stages. Although they considered those three lineages to merit species recognition, they did not propose specific taxonomic changes in that paper. We have placed the name "*gilberti*" in quotation marks to indicate that it refers to a group composed of several species.

E. multivirgatus (Hallowell, 1857)—Many-lined Skink

E. m. epipleurotus Cope, 1880—Variable Skink

Hammerson (1999, Amphibians and Reptiles in Colorado, Univ. Press of Colorado) argued, based on diagnosability and the apparent absence of intergrades, that *Eumeces multivirgatus epipleurotus* (under the name *E. gaigeae*) is a different species than *E. m. multivirgatus*. We have refrained from adopting this proposal until a more rigorous study is conducted.

E. skiltonianus (Baird and Girard, 1852)—Western Skink

Richmond and Reeder (2002, Evolution 56: 1498–1513) presented evidence that the subspecies of *Eumeces skiltonianus*, as currently circumscribed, do not correspond with the boundaries of haplotype clades based on mitochondrial DNA. However, because those authors did not propose a revised subspecies taxonomy, and because resolution of that taxonomy requires more extensive geographic sampling, we have retained the existing subspecies taxonomy (e.g., Tanner, 1988, Cat. Am. Amph. Rept. 447.1).

Hemidactylus turcicus (Linnaeus, 1758)—Mediterranean House Gecko (Introduced)

Hemidactylus turcicus is established at numerous localities in the southern and eastern United States, including the states of Alabama (Mount, 1975, The Reptiles and Amphibians of Alabama, Auburn Univ. Agric. Exper. Stat.), Arizona (Robinson and Romack, 1973, J. Herpetol. 7: 311–312), Arkansas (Paulissen and Buchanan, 1990, Herpetol. Rev. 21: 22), California (Porter, 1988, San Diego Herpetol. Soc. Newsl. 10: 5), Florida (Wilson and Porras, 1983, Univ. Kansas Mus. Nat. Hist. Spec. Publ. 9: 1–89 and references therein), Georgia (Bechtel, 1983, Herpetol. Rev. 14: 27–28), Louisiana (Etheridge, 1952, Copeia 1952: 47–48), Maryland (Norden and Norden, 1989 [1991], Maryland Nat. 33: 57–58), Mississippi (Keiser, 1984, J. Mississippi Acad. Sci. 29: 17–18), Nevada (Saethre and Medica, 1993, Herpetol. Rev. 24: 154–155), New Mexico (Painter et al., 1992, Herpetol. Rev. 23: 62), Oklahoma (Henniger and Black, 1987, Bull. Oklahoma Herpetol. Soc. 12: 20), South Carolina (Eason and McMillan, 2000, Herpetol. Rev. 31: 53), Texas (Conant, 1955, Am. Mus. Novit. 1726: 1–6), and Virginia (Knight, 1993, Dactylus 2: 49–50). Subspecific identifications (*H. t. turcicus*) have been reported in some cases, but not in others.

Holbrookia Girard, 1851—LESSER EARLESS LIZARDS

Taxonomy for *Holbrookia* follows Smith (1946, Handbook of Lizards. Lizards of the United States and Canada, Cornell Univ. Press) with modifications by Axtell (1956, Bull. Chicago Acad. Sci 10: 163–179; description of *H. maculata perspicua* and treatment of *H. lacerata* as a species) and those described in subsequent notes. Separation of *Cophosaurus texanus* (*Holbrookia texana*) from *Holbrookia* follows Axtell (1958, Ph.D.

dissertation, Univ. Texas), Clarke (1965, Emporia St. Res. Stud. 13: 1–66), Cox and Tanner (1977, Great Basin Nat. 37: 35–56) and de Queiroz (1989, Ph.D. dissertation, Univ. California, Berkeley).

H. elegans Bocourt, 1874—Elegant Earless Lizard

H. e. thermophila Barbour, 1921—Sonoran Earless Lizard

Holbrookia elegans was recognized as a species by Lowe (1964, pp. 153–174 in The Vertebrates of Arizona, C. H. Lowe [ed.], Univ. Arizona Press), and corroborating evidence has been provided by Adest (1978, Ph.D. dissertation, Univ. California, Los Angeles) and Wilgenbusch and de Queiroz (2000, Syst. Biol. 49: 592–612); a diagnosis has been provided by Axtell (1998, Interpretive Atlas of Texas Lizards 18: 1–19).

Lacerta bilineata Daudin 1802—Western Green Lizard (Introduced)
Amann et al. (1997, Salamandra 33: 255–268) presented evidence for the specific separation of *Lacerta bilineata* from *L. viridis*, and Green Lizards reported from Shawnee Co., Kansas (Collins, 1993, Univ. Kansas Mus. Nat. Hist. Public Educ. Ser. No. 13; Gubanyi and Gubanyi, 1997, Herpetol. Rev. 28: 96) have subsequently been referred to *L. bilineata* without a subspecific identification (Gubanyi, 2000, Trans. Kansas Acad. Sci. 103: 191–192; Kalyabina-Hauf and Deichsel, 2002, Herpetol. Rev. 33: 225–226).

Leiocephalus carinatus Gray, 1827—Northern Curly-tailed Lizard (Introduced)

L. c. armouri Barbour and Shreeve, 1935—Little Bahama Curly-tailed Lizard (Introduced)

Leiocephalus carinatus armouri is established in Brevard, Dade, and Palm Beach Counties, Florida (Wilson and Porras, 1983, Univ. Kansas, Mus. Nat. Hist. Spec. Publ. 9: 1–81 and references therein; Krysko and King, 2002, Herpetol. Rev. 33: 148).

Mabuya Fitzinger, 1826—MABUYAS

M. multifasciata (Kuhl, 1820)—Many-striped Mabuya (Introduced)
Mabuya multifasciata is established in Dade County, Florida (Meshaka, 1999, Florida Sci. 62: 153–157).

Neoseps Stejneger, 1910—FLORIDA SAND SKINKS
Taxonomy for *Neoseps* follows Telford (1969, Cat. Am. Amph. Rept. 80). Richmond and Reeder (2002, Evolution 56: 1498–1513) presented evidence that *Neoseps* is nested within *Eumeces*, closely related to *E. egregius*, though they did not propose a taxonomic change.

Ophisaurus Daudin, 1803—GLASS LIZARDS
Taxonomy for *Ophisaurus* follows McConkey (1954, Bull. Florida St. Mus. Biol. Sci. 2: 13–23) with modifications by Palmer (1987, Herpetologica, 43: 415–423; description of *O. mimicus*). Macey et al. (1999, Mol. Phylogenet. Evol. 12: 250–272) presented evidence that *Ophisaurus*, if it includes North American, European, African, and Asian species, is not monophyletic. Although they favored placing all species in *Anguis*, this action is both disruptive and makes *Anguis* redundant with Anguinae; we have therefore adopted their alternative proposal of retaining *Ophisaurus* for the North American and Southeast Asian species.

Phrynosoma douglasii (Bell, 1829)—Pygmy Short-horned Lizard

Podarcis muralis (Laurenti, 1768)—Common Wall Lizard (Introduced)
Podarcis muralis is established in Hamilton Co. (Cincinnati), Ohio (Vigle, 1977, Herpetol. Rev. 8: 19; Hedeen, 1988, Herpetol. Rev. 19: 19) and Kenton Co., Kentucky (Ferner and Ferner, 2002, Herpetol. Rev. 33: 226).

P. sicula (Rafinesque, 1810)—Italian Wall Lizard (Introduced)
Podarcis sicula is established in Long Island, New York (Smith and Kohler, 1978, Trans. Kansas Acad. Sci. 80: 1–24 and reference therein) and Topeka, Kansas (Collins, 1993, Univ. Kansas Mus. Nat. Hist. Public Edu. Ser. No. 13). According to Smith and Kohler (*op. cit.*), the New York population is *P. s. sicula*; however, a more recent study by Oliverio et al. (2001, Ital. J. Zool. 68: 121–124) referred both the New York (see also Burke et al., 2002, Copeia 2002: 836–842) and Kansas populations to *P. s. campestris*, though a more thorough characterization of geographic variation within *P. sicula* is needed. A population of *P. s. campestris* was formerly established in Philadelphia, Pennsylvania, but that population is now thought to be extinct (Smith and Kohler, *op. cit.* and references therein).

Sauromalus ater Duméril, 1856—Common Chuckwalla
A proposal to grant the name *Sauromalus obesus* (Baird, 1858) precedence over *S. ater* Duméril 1856 in the interest of maintaining nomenclatural stability (Montanucci et al., 2001, Bull. Zool. Nomen. 58: 37–40) is not followed because both names were in use prior to their treatment as synonyms by Hollingsworth (1998, Herpetol. Monog. 12: 38–191). For further discussion see McDiarmid et al. (2002, Bull. Zool. Nomen. 59: 45–48).

Sceloporus jarrovii Cope, 1875—Yarrow's Spiny Lizard
Wiens et al. (1999, Evolution 53: 1884–1897; see also Wiens and Penkrot, 2002, Syst. Biol. 51: 69–91) presented evidence that several of the previously recognized subspecies of *Sceloporus jarrovii* are not monophyletic and that several clades within this species are more closely related to other species in the *S. torquatus* group than to other populations of *S. jarrovii*. Therefore, they recognized five species for the populations formerly referred to *S. jarrovii*, applying the name *S. jarrovii* to the only one of those five species that occurs in the United States (corresponding with the set of populations formerly referred to *S. j. jarrovii*). No subspecies were recognized.

S. undulatus (Bosc and Daudin *in* Sonnini and Latreille, 1801)—Eastern Fence Lizard
Leaché and Reeder (2002, Syst. Biol. 51: 44–68) presented phylogeographic evidence that *Sceloporus undulatus*, as previously circumscribed, is made up of at least four separately evolving lineages, and they applied the name *S. undulatus* to populations east of roughly the 88th meridian. Their results also suggest that the formerly recognized subspecies *undulatus* (Southern Fence Lizard) and *hyacinthinus* (Northern Fence Lizard) are not natural groups (see also Miles et al., 2002, Herpetologica 58: 277–292), and that the deepest genetic division within *S. undulatus* is not between northern and southern populations but between those east and west of the Appalacian Mountains, though they did not recognize subspecies within *S. undulatus*.

S. consobrinus Baird and Girard, 1853—Prairie Lizard
See note for *Sceloporus undulatus*. Leaché and Reeder (2002, Syst. Biol. 51: 44–68) applied the name *S. consobrinus* to the populations formerly referred to *S. undulatus* from the central United States, most (though not all) of which occur in the plains between the Mississippi River and the Rocky Mountains. Their results also suggest that the formerly recognized subspecies *consobrinus* (Southern Prairie Lizard) and *garmani* (Northern Prairie Lizard) are not natural groups, and they did not recognize subspecies within *S. consobrinus*. Leaché and Reeder (*op. cit.*) noted that the name *S. thayerii* Baird and Girard 1852 (type locality: Indianola, Calhoun Co., TX) may turn out to be the correct name of this species and that populations east of the Mississippi River along the Gulf Coast may represent a separate species.

S. cowlesi Lowe and Norris, 1956—Southwestern Fence Lizard
See note for *Sceloporus undulatus*. Leaché and Reeder (2002, Syst. Biol. 51: 44–68) applied the name *S. cowlesi* to the populations formerly referred to *S. undulatus* from roughly the region of the Chihuahuan Desert. They did not recognize subspecies within *S. cowlesi*.

S. tristichus Cope *in* Yarrow 1875—Plateau Lizard
See note for *Sceloporus undulatus*. Leaché and Reeder (2002, Syst. Biol. 51: 44–68) applied the name *S. tristichus* to the populations formerly referred to *S. undulatus* from roughly the region of the Colorado Plateau. Their results also suggest that the formerly recognized subspecies *tristichus* (Southern Plateau Lizard), *erythrocheilus* (Red-lipped Plateau Lizard), and *elongatus* (Northern Plateau Lizard) are not natural groups, and they did not recognize subspecies within *S. tristichus*.

Scincella lateralis (Say in James, 1823)—Little Brown Skink

Uma notata Baird, 1859 "1858"—Colorado Desert Fringe-toed Lizard

Trépanier and Murphy (2001, Mol. Phylogenet. Evol. 18: 327–334) presented evidence that *Uma notata*, as previously circumscribed, is paraphyletic; the subspecies *U. n. notata* is more closely related to *U. inornata* than to *U. n. rufopunctata* (see also Wilgenbusch and de Queiroz, 2000, Syst. Biol. 49: 592–612). They therefore considered the two previously recognized subspecies to be species.

U. rufopunctata Cope, 1895—Yuman Desert Fringe-toed Lizard
See note for *Uma notata*. Populations formerly assigned to *U. rufopunctata* from the Mohawk Dunes, Yuma Co., Arizona appear to represent a currently undescribed cryptic species (Trépanier and Murphy, 2001, Mol. Phylogenet. Evol. 18: 327–334).

Urosaurus nigricaudus (Cope, 1864)—Baja California Brush Lizard
Aguirre et al. (1999, Herpetologica 55: 369–381) and Grismer (1999, Herpetologica 55: 446–469) presented evidence that *Urosaurus microscutatus* and *U. nigricaudus* constitute a single species, for which the name *U. nigricaudus* has priority and within which no subspecies were recognized. The English name Black-tailed Brush Lizard was applied to *U. nigricaudus* when that species was thought to include only populations from southern Baja California; however, that name is descriptively misleading when applied to the species as currently circumscribed. Although the English name Baja California Brush Lizard has been used for *U. lahtelai* (e.g., Stebbins, 1985, A Field Guide to Western Reptiles and Amphibians, Houghton Mifflin Co.; Grismer, 2002, Amphibians and Reptiles of Baja California, Univ. California Press), that species is restricted to a small area in the vicinity of Cataviña (suggesting the English name Cataviña Brush Lizard); in contrast, *U. nigricaudus* is widely distributed in, and more-or-less restricted to, Baja California.

Uta stansburiana Baird and Girard, 1852—Common Side-blotched Lizard
Upton and Murphy (1997, Mol. Phylogenet. Evol. 8: 104–113) presented evidence for a distant relationship between *Uta* specimens from Durango versus those from Baja California and surrounding islands (as well as one locality in western Sonora), and they considered the Durango population to constitute a different species, to which they applied the name *U. stejnegeri*. Upton and Murphy's study did not include any populations from the United States, where *Uta* is widely distributed (including the type localities of both *stanburiana* and *stejnegeri*), and we have therefore refrained from adopting their taxonomic proposal until more information is obtained on the relationships of the United States populations.

Xantusia bezyi Papenfuss, Macey, and Schulte, 2001—Bezy's Night Lizard

X. gracilis Grismer and Galvan, 1986—Sandstone Night Lizard
Lovich (2001, Herpetologica 57: 470–487), presented evidence that the population formerly designated *Xantusia henshawi gracilis* is evolving separately from other populations of *X. henshawi* and recognized it as a species.

X. henshawi Stejneger, 1893—Granite Night Lizard
Lovich (2001, Herpetologica 57: 470–487) presented evidence that the populations of *Xantusia henshawi* represent at least three separately evolving lineages, though he did not propose recognizing them as species.

X. vigilis Baird, 1859 "1858"—Desert Night Lizard

X. v. arizonae Klauber, 1931—Arizona Night Lizard
Papenfuss et al. (2001, Sci. Pap. Nat. Hist. Mus. Univ. Kansas 23: 1–9) proposed that *X. v. arizonae* represents a different species than other populations of *X. vigilis* based on DNA and allozyme differences. Their study was based on a limited sample of *X. vigilis*, and we have therefore refrained from adopting their proposal until more information becomes available on the relationships of other *X. vigilis* populations.

Squamata — SNAKES

Compiled by Jeff Boundy, Jonathan Campbell, Brian Crother (Chair)

Charina umbratica Klauber, 1943—Southern Rubber Boa
Rodríguez-Robles et al. (2001, Mol. Phylogenet. Evol. 18: 227–237), used mtDNA sequence and considered allozyme data from a previous study (Weisman, 1988, MS Thesis, CSU Polytechnic Pomona) and found *C. b. umbratica* to represent a morphologically distinct, allopatric entity that they elevated to species status.

Chilomeniscus stramineus Cope, 1860—Variable Sandsnake
Grismer et al. (2002, Herpetologica 58:18–31) found *C. cinctus, C. punctatissimus, and C. stramineus* to represent morphotypes of a single species.

Chionactis Cope, 1860—SHOVEL-NOSED SNAKES
Reviewed by Mahrdt et al. (2001, Cat. Am. Amph. Rept. 730).

C. occipitalis (Hallowell, 1854)—Western Shovel-nosed Snake
Reviewed by Mahrdt et al. (2001, Cat. Am. Amph. Rept. 731).

C. o. annulata (Baird, 1859)—Colorado Desert Shovel-nosed Snake
Mahrdt et al. (2001, Cat. Am. Amph. Rept. 730) considered *C. saxatilis* a synonym of *C. o. annulata*.

C. palarostris (Klauber, 1937)—Sonoran Shovel-nosed Snake
Reviewed by Mahrdt et al. (2001, Cat. Am. Amph. Rept. 732).

Contia tenuis (Baird and Girard, 1852)—Sharp-tailed Snake
Hoyer (2001, Northwest. Nat. 82: 116–122) found *C. tenuis* to comprise two morphological species. Molecular data presented by Feldman and Spicer (2002, J. Herpetol. 36: 648–655) support recognition of two species, but the new species remains undescribed.

Crotalus oreganus Holbrook, 1840—Western Rattlesnake
Pook et al. (2000, Mol. Phylogenet. Evol. 15: 269–282), Ashton and de Queiroz (2001, Mol. Phylogenet. Evol. 21: 176–189), and Douglas et al. (2002, pp. 11–50 *in* Biology of the Vipers, G. W. Schuett, M. Höggren, M. E. Douglas, and H. W. Greene [eds.], Eagle Mountain Press) analyzed mtDNA sequence data and concluded that *Crotalus viridis* comprised at least two clades, *C. viridis* and *C. oreganus*, with *C. v. cerberus* being the sister taxon to populations of *C. oreganus*. The former two studies did not formally recognize *cerberus* as a species, although both suggested that it was an evolutionary species based on sequence differences and allopatry. The last study did recognize *cerberus* as well as four other taxa. We take the conservative action supported by the congruence among all three studies, which is the recognition of *viridis* and *oreganus*.

C. o. abyssus Klauber, 1930—Grand Canyon Rattlesnake

C. o. cerberus (Coues, 1875)—Arizona Black Rattlesnake

C. o. concolor Woodbury, 1929—Midget Faded Rattlesnake

C. o. helleri Meek, 1905—Southern Pacific Rattlesnake

C. o. lutosus Klauber, 1930—Great Basin Rattlesnake

C. o. oreganus Holbrook, 1840—Northern Pacific Rattlesnake

C. ruber Cope, 1892—Red Diamond Rattlesnake
The International Commission on Zoological Nomenclature (2000, Bull. Zool. Nomencl. 57: 189–190. Opinion 1960) has ruled that the name *Crotalus ruber* Cope 1892 take precedence over *C. exsul* when used as a specific epithet.

C. scutulatus (Kennicott, 1861)—Mohave Rattlesnake

C. s. scutulatus (Kennicott, 1861)—Northern Mohave Rattlesnake
The spelling of the word "Mojave" has been changed to its proper form, "Mohave." The misspelling was noted by Lowe in the preface to his "Venomous Reptiles of Arizona" (1986). The English name of the nominal subspecies has been changed to reflect the distribution rather than describe rattlesnakes from a small portion of its distribution (D. Hardy and H. Greene, pers. comm.).

C. viridis (Rafinesque, 1818)—Prairie Rattlesnake
See comments under *C. oreganus*.

C. v. nuntius Klauber, 1935—Hopi Rattlesnake

C. v. viridis (Rafinesque, 1818)—Green Prairie Rattlesnake

Drymarchon melanurus (Duméril, Bibron and Duméril, 1854)—Central American Indigo Snake
Wüster et al. (2001, Herpetol. J. 11: 157–165) found two taxa of

Drymarchon coexisting in northern Venezuela, representing South American (*D. corais*) and Central/North American (*D. melanurus*) taxa.

D. m. erebennus (Cope, 1860)—Texas Indigo Snake

Elaphe Fitzinger, 1833—RATSNAKES
Utiger et al. (2002, Russian J. Herpetol. 9: 105–124), using molecular data, divided *Elaphe* into eight genera. New World *Elaphe* are part of a clade outside of Old World species, and *Pantherophis* Fitzinger, 1843, is resurrected for most North American species. The common name would be North American Ratsnakes. Pending further review, we retain the current concept of *Elaphe*.

E. alleghaniensis (Holbrook, 1836)—Eastern Ratsnake
See under *E. obsoleta*.

E. emoryi (Baird and Girard, 1853)—Great Plains Ratsnake
Burbrink (2002, Mol. Phylogenet. Evol. 25: 465–476), using molecular data, found *E. guttata* to comprise three clades, which he elevated to species level. *Elaphe guttata meahllmorum* was inferred not to be an evolutionary entity, and was synonymized with *E. emoryi*.

E. guttata (Linnaeus, 1766)—Red Cornsnake
Burbrink (2002, Mol. Phylogenet. Evol. 25: 465–476), using molecular data, found *E. guttata* to comprise three clades, which he elevated to species level, restricting *E. guttata* to populations east of the Mississippi River.

E. obsoleta (Say, 1823)—Texas Ratsnake
Burbrink divided *E. obsoleta* into three species, with no subspecies, based on the congruence of morphological (2001, Herpetol. Monogr. 15: 1–53) and mtDNA (Burbrink et al. 2000, Evolution 54: 2107–2118) evidence.

E. slowinskii Burbrink, 2002—Slowinski's Cornsnake
Burbrink (2002, Mol. Phylogenet. Evol. 25: 465–476), using molecular data, found *E. guttata* to comprise three clades, which he elevated to species level. The clade comprising populations in western Louisiana and eastern Texas were named *E. slowinskii*.

E. spiloides (Duméril, Bibron and Duméril, 1854)—Gray Ratsnake
See under *E. obsoleta*.

Farancia erytrogramma (Palisot de Beauvois *in* Sonnini and Latreille, 1801)—Rainbow Snake

Gyalopion Cope, 1860—WESTERN HOOK-NOSED SNAKES

G. canum Cope, 1860—Chihuahuan Hook-nosed Snake

Heterodon gloydi Edgren, 1952—Dusty Hog-nosed Snake
Werler and Dixon (2000, Texas Snakes. University of Texas Press, Austin) regarded *H. n. gloydi* to be an allopatric, diagnosable taxon restricted to the low plains-eastern forest ecotone of eastern Texas.

Lampropeltis triangulum (Lacépède, 1789)—Milksnake

L. zonata (Lockington, 1876 ex Blainville, 1835)—California Mountain Kingsnake
Rodríguez-Robles et al. (1999, Mol. Ecol. 8: 1923–1934) examined mtDNA and color pattern. The DNA suggested distinct northern and southern clades that they left unnamed. The color pattern variation was too variable to differentiate the seven subspecies. We follow these data and do not recognize any subspecies at this time.

Leptotyphlops dissectus (Cope, 1896)—New Mexico Threadsnake
See *L. dulcis*.

L. dulcis (Baird and Girard, 1853)—Texas Threadsnake
Dixon and Vaughan (2003. Texas J. Sci. 55: 3–24), using morphological data, elevated *L. d. dissectus* to species status, and diagnosed three subspecies within the nominate race, one of which remains unnamed.

L. d. dulcis (Baird and Girard, 1853)—Plains Threadsnake

L. d. rubellum (Garman, 1883)—South Texas Threadsnake

Masticophis fuliginosus (Cope, 1895)—Baja California Coachwhip
On the basis of a sympatric occurrence with *M. flagellum*, Grismer (1994, Herpetol. Nat. Hist. 2: 51; 2002, Amphibians and Reptiles of Baja California. Univ. California Press, Berkeley) elevated *M. f. fuliginosus* to species status.

Opheodrys aestivus (Linnaeus, 1766)—Rough Greensnake
Reviewed by Walley and Plummer (2000, Cat. Am. Amph. Rept. 718).

Pituophis Holbrook, 1842—BULLSNAKES, GOPHERSNAKES, and PINESNAKES
Rodríguez-Robles et al. (2000, Mol. Phylogenet. Evol. 14: 35–50) used mtDNA data and corroborated the current view of *Pituophis* with three species: *melanoleucus*, *catenifer*, and *ruthveni*. However, the recognition of *ruthveni* rendered *catenifer* paraphyletic. Pending data to corroborate the mtDNA, it is clear that *Pituophis* will undergo taxonomic revision in the near future.

P. catenifer (Blainville, 1835)—Gophersnake
Rodriguez-Robles et al. (2000, Mol. Phylogenet. Evol. 14: 35–50), used mtDNA data and discovered significant internal structuring among *P. catenifer* populations, which may signify the existence of additional species. Rodriguez-Robles et al. did not attempt reclassification. See annotation under *Pituophis*.

P. ruthveni Stull, 1929—Louisiana Pinesnake
Rodriguez-Robles et al. (2000, Mol. Phylogenet. Evol. 14: 35–50), used mtDNA data and argued for the recognition of *P. ruthveni*, despite lack of significant or independent differentiation from some populations of *P. c. sayi*.

Regina Baird and Girard, 1853—CRAYFISH SNAKES
Alfaro and Arnold (2001, Mol. Phylogenet. Evol. 21: 408–423) used DNA sequence data and found the genus to be grossly polyphyletic. This conclusion corroborates the allozyme-based hypothesis of Lawson (1985, Ph.D. dissertation, Louisiana State University). Taxonomic change is necessary for this genus but Alfaro and Arnold recommended against such change pending further investigation of their relationships. Reviewed by Ernst et al. (2002, Cat. Am. Amph. Rept. 756).

R. septemvittata (Say, 1825)—Queen Snake
Reviewed by Ernst (2002, Cat. Am. Amph. Rept. 757).

Sonora semiannulata Baird and Girard, 1853—Groundsnake
Werler and Dixon (2000. Texas Snakes. University of Texas Press, Austin) recognized the subspecies *S. s. taylori* as a diagnosable taxon occupying the Tamaulipan biotic province.

S. s. semiannulata Baird and Girard, 1853—Variable Groundsnake

S. s. taylori (Boulenger, 1894)—Southern Texas Groundsnake

Storeria occipitomaculata (Storer, 1839)—Red-bellied Snake
Reviewed by Ernst (2002, Cat. Am. Amph. Rept. 759).

Tantilla cucullata Minton, 1956—Trans-Pecos Black-headed Snake
Reviewed by Wilson et al. (2000, Cat. Am. Amph. Rept. 719).

T. elegans (Baird and Girard, 1853)—Terrestrial Gartersnake
Bronikowski and Arnold (2001, Copeia 2001: 508–513) used cytochrome b sequence data to identify several clades within *T. elegans* that did not, in some cases, follow phenotypic subspecies boundaries. Hammerson (1999, Amphibians and Reptiles of Colorado. 2nd ed. University of Colorado Press, Boulder) found phenotypes assignable to *T. e. arizonae* and *T. e. vascotanneri* outside of their purported distributions within Colorado, and recommended that the two names be synonymized with *T. e. vagrans*. Hammerson's data supported similar action for Arizona and New Mexico populations as well (J. Boundy, pers. obs.). Three subspecies are tentatively retained.

T. e. elegans (Baird and Girard, 1853)—Mountain Gartersnake

T. e. terrestris Fox, 1951—Coast Gartersnake

T. e. vagrans (Baird and Girard, 1853)—Wandering Gartersnake

T. sirtalis infernalis (Blainville, 1835)—Red-spotted Gartersnake
The International Commission on Zoological Nomenclature (2000, Bull. Zool. Nomencl. 57: 191–192. Opinion 1961) has ruled that the name *Coluber infernalis* be re-associated with Pacific Coast populations referred to as *T. s. concinnus* by Crother et al. (2000, Herpetol. Circular 29:73).

T. s. tetrataenia (Cope, 1875)—San Francisco Gartersnake

Action by the International Commission on Zoological Nomenclature (2000, Bull. Zool. Nomencl. 57: 191–192. Opinion 1961) has retained the name *Eutaenia sirtalis tetrataenia* for San Francisco Peninsula populations of *T. sirtalis*.

CROCODILIA—CROCODILIANS

Crocodylus acutus Cuvier, 1807—American Crocodile

TESTUDINES—TURTLES

Compiled by John Iverson, Peter Meylan (Chair), Michael Seidel

Actinemys Agassiz, 1857—PACIFIC POND TURTLES
Emys and *Emydoidea* are retained despite the recommendation of Feldman and Parham (2002) to lump *Emydoidea* and *Actinemys* under *Emys* because those authors had not seen the argument by Holman and Fritz (2001) for recognizing *Actinemys* as a monotypic genus. We are in agreement with Holman and Fritz that retention of separate genera for *Emys* and *Emydoidea*, and using a third generic name for *Actinemys marmorata*, best serves to reflect the diversity in this monophyletic group. See *Clemmys*.

A. marmorata (Baird and Girard, 1852)—Pacific Pond Turtle

A. m. marmorata (Baird and Girard, 1852)—Northern Pacific Pond Turtle

A. m. pallida (Seeliger, 1945)—Southern Pacific Pond Turtle

Clemmys Ritgen, 1828—SPOTTED TURTLES
Until recently (Holman and Fritz, 2001, Zoolog. Abhand. Staat. Mus. für Tierkunde Dresden 51: 331–354; and Feldman and Parham, 2002, Mol. Phylogenet. Evol. 22: 388–398) the content of the genus *Clemmys* was based on the work of McDowell (1964, Proc. Zool. Soc. Lond. 143: 239–279). This genus was considered to include a set of four North American species (*C. guttata, C. insculpta, C. marmorata*, and *C. muhlenbergii*) and was given the Standard English name, AMERICAN POND TURTLES. Work by Bickham et al (1996, Herpetologica 52: 89–97), Burke et al. (1996, Herpetologica 52: 572–584), Lenk et al. (1999, Mol. Ecol. 8: 1911–1922), Holman and Fritz (op. cit.), Feldman and Parham (op. cit.) and Seidel (2002a, Copeia 2002: 1118–1121) provide ample evidence that *Clemmys* (*sensu lato*) is paraphyletic with respect to the genera *Emys, Emydoidea* and *Terrapene*. *C. marmorata* has been shown to be the sister group of *Emys* and *Emydoidea* with the remaining species being paraphyletic with respect to this group and *Terrapene. C. insculpta* and *C. muhlenbergii* appear to be sister taxa and *C. guttata* appears to be the sister group to all remaining members of the Emydinae. Thus, the taxonomic revision suggested by Holman and Fritz (op. cit.) is advisable and is followed here. In this revision only the type species, *C. guttata*, is retained in the genus *Clemmys*. See notes for *Actinemys* and *Glyptemys*.

C. guttata (Schneider, 1792)—Spotted Turtle

Reviewed by Ernst (1972, Cat. Am. Amph. Rept. 124).

Glyptemys Agassiz, 1857—SCULPTED TURTLES
See note for *Clemmys*.

G. insculpta (LeConte, 1830)—Wood Turtle

G. muhlenbergii (Schoepff, 1801)—Bog Turtle

Kinosternon hirtipes Wagler, 1830—Rough-footed Mud Turtle

Sternotherus carinatus (Gray, 1855 1856)—Razor-backed Musk Turtle

Trachemys Agassiz, 1857—SLIDERS
Content of this genus follows Seidel and Smith (1986, Herpetologica 42: 242–248) and Seidel (2002a, J. Herpetol. 36: 285–292).

T. gaigeae (Hartweg, 1939)—Mexican Plateau Slider

Price and Hillis (1989, First World Congr. Herpetol. Abstract), Seidel et al. (1999, Herpetologica 55: 470–487), and Seidel (2002b, J. Herpetol. 36:285–292) provide evidence for the specific recognition of this form.

T. g. gaigeae (Hartweg, 1939)—Big Bend Slider

Herpetological Review, 2003, 34(3), 203–206.

Vocalization and Diet of *Syncope antenori* (Amphibia: Anura: Microhylidae)

College Station, Texas 77843-2258, USA
e-mail: vrm2111@neo.tamu.edu

and

PATRICIA VARGAS
Department of Biology, Texas A&M University
College Station, Texas 77843, USA

Syncope is a microhylid frog genus composed of two very small species, *Syncope antenori* Walker 1973 and *S. carvalhoi* Nelson 1975, distributed in the Amazonian region of Perú (Morales 1995), Brazil, and Ecuador. Because these frogs are small and are infrequently found, little is known of their life history. Several authors cited some aspect of the reproductive mode of *S. antenori* (Duellman 1978; Krüegel and Richter 1995; Zimmerman and Simberloff 1996), and Duellman (1978) suggested that this species might be mute because of the absence of vocal slits in males. Regarding diet, Duellman (*op. cit.*) reported that 6 of 7 individuals examined fed on ants and mites, without more detail.

We describe the vocalization of *S. antenori* and provide additional diet data. From October to November 1995, we conducted a biological inventory on the west-central side of the Cordillera El Sira, between the Samantoshoari and Saberoshoari Creeks (elevation 210 m, approximately 09°59'S, 74°40'W). The site was located 5 km SE of the Native Community Davis (approx. 09°58'S,

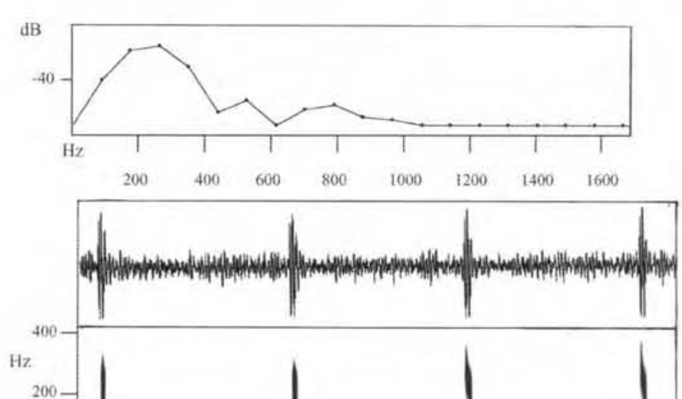

FIG. 1. Vocalization of *Syncope antenori* (Microhylidae), MUSM 17014, from Cordillera El Sira, Pasco, Perú (recorded at 22.5°C). Frequency spectrum (above), oscillogram (middle), sonogram (below) of advertisement call. Hz = Hertz, msec = milliseconds.

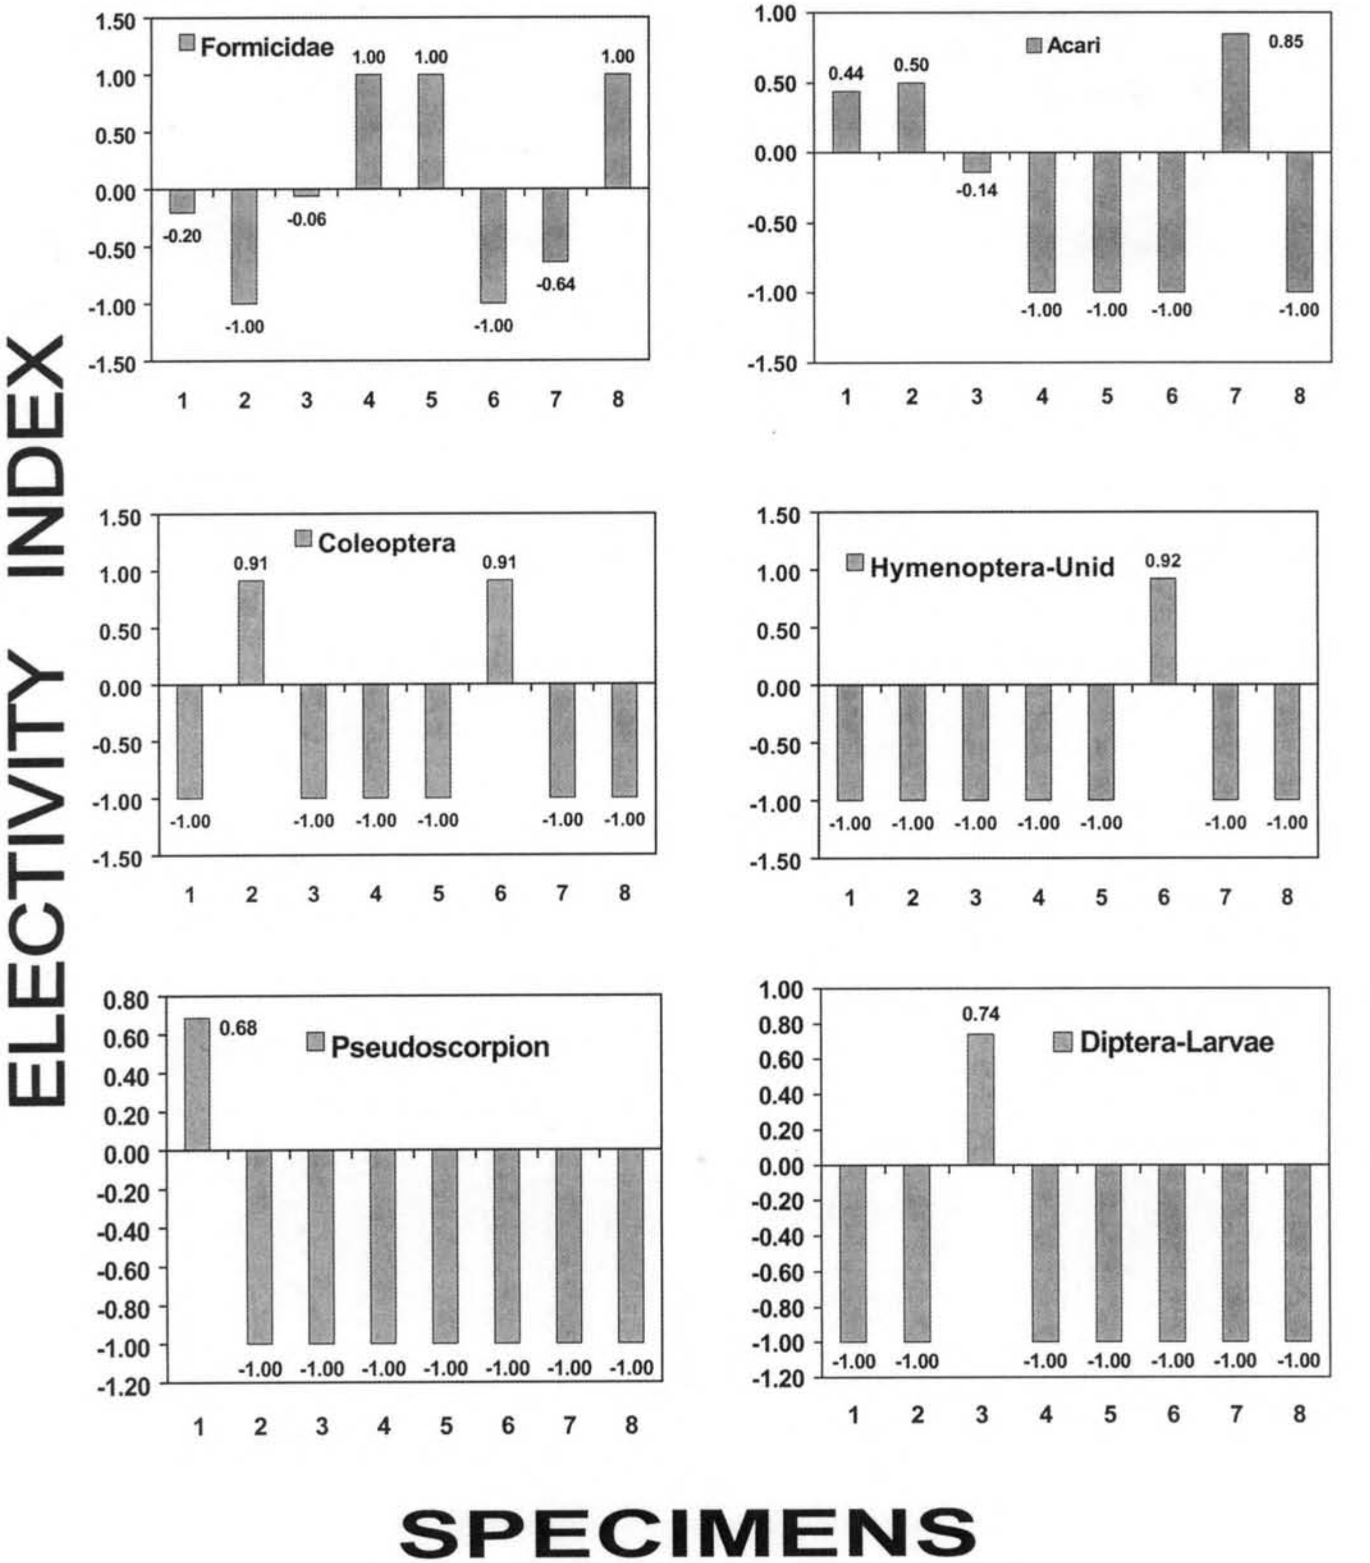

FIG. 2. Stomach contents of *Syncope antenori* (Microhylidae) from Cordillera El Sira, Pasco, Perú.. See Table 1 for explanation of the specimen numbers.

74°43'W) on the Aporucayali River, a tributary of the Pichis River, Oxapampa Department, Pasco, Perú. We recorded calls and made observations of the ecology and behavior of *S. antenori*. Vocalizations were recorded with an AVR General Electric® mini-cassette recorder; air temperature at the time of recording (2000–2300 h) was 22.5°C. Call analysis was done using Canary 1.2.4 (Charif et al. 1995). Specimens were deposited in the Museo de Historia Natural de la Universidad Nacional Mayor de San Marcos (MUSM 17014–17021).

Call analysis.—Snout–vent length (SVL, mean ± SD) of males

was 12.0 ± 0.3 (N = 6), and female SVL was 13.5 ± 0.5 (N = 2). At El Sira, males of this species called in the leaf litter at night. The low vocalization was almost imperceptible to the human ear, and can be described as a light constant and metallic tapping, "tic, tic, tic." Two males in the field and one captive male were recorded as they called in a plastic bag. There was no significant variation in call characteristics under either natural conditions or in captivity. The advertisement call of *S. antenori* consisted of a series of short notes with a total duration of 10–16 sec. Each note had a duration of 6.3–7.2 msec (mean ± SD: 6.9 ± 0.3, N = 23 calls or notes of two individuals). The call frequency extended from 222 to 634 Hz, with a peak at 375 Hz, and the time interval between calls was from 210 to 234 msec (225 ± 0.4, N = 23 calls or notes of two individuals; Fig. 1). The factor that influences the call frequency in frogs may be the speed of sound within the vocal cavity or vocal sacs (Rand and Dudley 1993). All calling males of *S. antenori* did not have vocal slits and vocal sacs, and their call frequency was relatively low. We observed two specimens singing with their mouths open, most likely expelling air, causing the sound. These frogs may use the oral cavity like a resonator, because this species lacks vocal sacs for this function. This is in contrast to another minute frog, *Phyzelaphryne miriamae* (Leptodactylidae), which had a higher call frequency (2810–4460 Hz), vocal slits and sacs, and called with a closed mouth (Heyer and Gascon 1995).

Diet analysis.—We examined stomach contents of eight specimens. Ants (Subfamilies Mirmicinae and Dolicoderinae) and mites comprised 83% of the diet. Coleoptera, unidentified Hymenoptera, and Pseudoscorpiones formed a much smaller portion of the diet (Table 1). We used the Jacobs (1974) electivity index for the seven most common items eaten, $D = (r-p)/(r+p)-2(rp)$; "r" was the proportion of each item per specimen by the total sum of all items in each specimen. The estimation of the proportion of any item in the environment (p) was calculated by dividing the sum of each item from all the specimens by the total sum of all items found in the specimens. The electivity index value of each item for each specimen ranges from no preference or not eaten (-1) to an exclusive preference or eaten nearly exclusively (+1). The electivity index is "0" when items are eaten in equal proportions. From the diet analysis, it appears that *S. antenori* principally feed on ants, which formed 69% of the total items found in 6 of 8 specimens (Table 1). However, only three specimens had an electivity index indicating exclusive preference (+1) for ants. Another three showed less preference (from -0.64 to -0.06) while two showed no preference for ants (-1), but preferred coleopterans instead (+0.91, Fig. 2). Four of eight specimens ate mites, 14% of the total of items (Table 1), but only three showed a positive electivity index for this prey item (Fig. 2). These results are in contrast to Simon and Toft (1991) who mentioned that the preference for mites was strongly associated with species of small size, and with juvenile frogs rather than adults. We found that half of the *S. antenori* specimens had a diverse diet, including not only ants and/or mites but other taxa (Table 1). These frogs may be choosing prey types independently of prey size (Lima 1998; Lima and Moreira 1993).

Lastly, frog mobility was relatively great, considering the small size of this species. We observed at least two specimens moving slowly within an area of 1.5 m^2 for ca. 20 min. We suggest that *S. antenori* is a relatively widely foraging species (Huey and Pianka 1981) and is opportunistic in terms of prey preference.

Acknowledgments.—We are grateful to the Tratado de Cooperación Amazónica (TCA), Comisión Especial de Asuntos Indígenas de la Amazonía, Apatyawaka Nampitsi Ashaninka Pichis (ANAP), and Asociación de Ecología y Conservación (ECCO) for supporting our expedition to the El Sira Cordillera. We thank Eusebio López Mishari, Samuel Pérez Piahuantze, Antonio González Urday, Anthony Luscombe, and Simón Pérez and his wife for their help on the expedition. P. Teel and J. Cook, of the Entomology Department of Texas A&M University, assisted with arthropod identification. Janalee W. Caldwell, Deanna H. Olson, Barbara Zimmerman, and Albertina Lima reviewed the manuscript.

Identification of Marine Turtle Nesting Beaches on the Mediterranean Coast of Sinai, Egypt

MICHAEL CLARKE*

and

ANDREW C. CAMPBELL

The majority of sandy beaches in the Mediterranean have been surveyed to determine the location of marine turtle nesting areas. Detailed information is available on the status of green (*Chelonia mydas* L.) and loggerhead (*Caretta caretta* L.) turtle populations nesting in northern Cyprus (Broderick and Godley 1996; Glen et al. 1996; Godley et al. 1996), southern Cyprus (Demetropoulos and Hadjichristophorou 1989, 1995), Greece (Margaritoulis 1983; Arianoutsou 1988), Israel (Kuller 1995, 1999), Libya (Laurent et al. 1995, 1997; Venizelos 1996), Syria (Kasparek 1995) and Turkey (Baran and Kasparek 1989; Coley and Smart 1992; Yerli and Demirayak 1996; Gerosa et al. 1998). In addition, a comprehensive synopsis of the status of marine turtles in the Eastern Mediterranean region can be found in Kasparek (2001).

In recent years the coast of Egypt has received less attention than its eastern Mediterranean neighbors such as Israel and Libya, consequently the exact status of nesting populations in this region is unclear. Preliminary surveys of the coastline between the city of Alexandria and the Libyan border (western region; Fig. 1) performed by Kasparek (1993), indicated that negligible marine turtle nesting activity was occurring in this region. We confirmed this in 1998 while conducting a survey of the entire Mediterranean coast of Egypt (Clarke et al. 2000), finding only limited circumstantial evidence (i.e., three sets of emergence tracks and no nests) of nesting activity in the western region. Similarly, no evidence of nesting was found in the Nile Delta (central region; Fig. 1), during the 1998 survey.

Evidence was found however, that a small population of green and loggerhead turtles were nesting on beaches of the Sinai in eastern Egypt, close to the border with Israel. In this paper we document the results of a three-year study to quantify the extent of marine turtle nesting activity occurring along the Sinai coast between the border town of Rhafa to the east, and Port Said to the west (eastern region; Fig. 1).

Methods.—The Mediterranean coast of the Sinai measures 220 km from the Israeli border to the Suez Canal at Port Said; of this section, 200.7 km is sandy beach with potentially suitable habitat for marine turtle nesting. Other than the two inlets to Bardawil lagoon (Fig. 2), the coast in this region is continuous sandy beach with few natural divisions; therefore, for the purposes of this survey it was arbitrarily divided into 19 beaches. The limits of these divisions were determined by the presence of an easily identifiable landmark, or as a length of coastline that could be surveyed in a convenient time period (details are given in Table 1 and Fig. 2). In the lagoon region (i.e., beaches 8–16; Fig. 2) only the north side of the outer sandbar was surveyed, as interviews with local fishermen revealed that marine turtles had never been observed nesting in the inner lagoon.

Total				200.7 km	

During the period from late May to mid-September (the main turtle nesting season in the eastern Mediterranean; Baran and Kasparek 1989; Demetropoulos and Hadjichristophorou 1995) all the beaches listed in Table 1 were surveyed during the early morning hours by two-person teams. Access to the beaches was not permitted at night. During the 1998 season, beaches were surveyed by walking from east to west, with one man on the waterline and the other following a parallel track 4–5 m landwards. However, because of the large distances involved subsequent surveys were performed using an all terrain vehicle (ATV), with two persons riding along the beach from east to west. One rider scrutinized the water line while the other surveyed the upper beach.

Early in the season, beaches were re-visited every two weeks until an emergence track was found. Thereafter a beach was visited twice weekly; thus no track recorded was more than four days old. This allowed for a reasonable estimate of the date of egg deposition, and gave a good prediction of the hatch date approximately 40 days later. The exact location of all emergence tracks was noted using a Magellen 2000 Global Positioning System (GPS). Under the climatic conditions encountered during the summer months, emergence tracks were still recognizable for up to three weeks. In addition, the Egyptian Coast Guard was enlisted to find emergence tracks as soldiers patrol every mile of the Sinai coast on a daily basis. Because of these two factors we have high confidence that

very few emergence tracks were overlooked during the survey.

The species of the emerging turtle was identified from track morphology—green turtles leave a regular pattern of imprints in the sand as they use both front flippers simultaneously to haul themselves across the beach. Conversely, loggerhead tracks are irregular as they use the front flippers in an alternating pattern to move on land (Demetropoulos and Hadjichristophorou 1995). The inside and outside widths of the tracks were recorded; the presence or absence of a body pit noted; and nests checked for egg deposition. Nests were then marked in a cryptic fashion to allow

relocation at a later date.

During the 1999 and 2000 seasons, return visits were made to the nests to check for hatching 40, 42, and 44 days after egg deposition. After hatching, the nests were excavated and an assessment made of the number of eggs laid, and hatching success. The curved carapace length (CCL) and species of dead stranded turtles, or parts of turtles, were also recorded throughout the survey.

Results.—Evidence was found that loggerhead and green turtles nest in the eastern region of the Mediterranean coast of the Sinai (Table 2). Emergence tracks and/or nests were found on 15 of the 19 beaches surveyed during the three-year study. Most of the activity was concentrated on beaches 1–7, situated at the eastern side of the study area (Table 3).

Loggerhead turtles utilized the area most heavily, with 20, 32, and 37 confirmed egg depositions being found in 1998, 1999, and 2000 respectively. Green turtles utilized the area to a lesser degree, with 1, 0, and 3 confirmed egg depositions being found during 1998, 1999, and 2000. No evidence of nesting by leatherback turtles (*Dermochelys coriacea*) was found (Table 2). The majority of stranded turtles were loggerheads (74), however, a small number of green (16) and leatherbacks (4) was also found.

Conclusions.—Loggerhead, green, and leatherback marine turtles are present in the waters off the Mediterranean coast of Egypt; as dead specimens of all three species were found washed ashore during the survey. Conclusive evidence was found that loggerhead and green turtles nest on the Mediterranean coast of the Sinai. No evidence was found to indicate that leatherback turtles nest in this area.

Most nests were located on an 83-km stretch of coastline close to the Israeli border (i.e., between beaches 1 to 7; 31°06'47"N/33°36'56"E to 31°16'20"N/34°08'37"E). Beaches 1, 2, 3, and 7 were the most heavily utilized areas, with 76% of all nests being found on these beaches over the three-year survey. Comparison of the levels of nesting activity in this region with that reported for the Mediterranean coast of Egypt as a whole (Clarke et. al. 2000; Kasparek 1993) indicates that the eastern Sinai is the primary marine turtle nesting region for the entire Mediterranean coast of Egypt.

The number of female loggerhead turtles nesting in this area is apparently small. Given that a single female will lay 1–3 clutches per season (Demetropoulos and Hadjichristophorou 1995), results suggest that only 10–20 individuals are nesting in the region each year. The number of green turtles utilizing this area is even lower, perhaps only one or two individuals per year. These results appear to be consistent with those reported from the adjacent Israeli coast. Kuller (1999) reports that during the 1998 nesting season, 40 loggerhead and 13 green turtle nests were found along a 190-km stretch of the Israeli Mediterranean coastline. However, this does appear to have been an exceptional year, as the annual mean number of nests found over the previous five-year period was only 27.4 loggerhead nests and 2.2 green turtle nests. These means are consistent with those found during our study of the Mediterranean coast of Sinai.

The mean number of eggs found in loggerhead nests on the Sinai coast (78.0 in 1998; 64.68 in 1999; and 64.26 in 2000) was within the range of 60–85 cited for nests from northern and southern Cyprus (Broderick and Godley 1996; Demetropoulos and Hadjichristophorou 1995). Generally, clutch sizes in the Mediterranean appear to be lower than in other parts of the world; e.g., Hirth (1980) reports the average global clutch size for *C. caretta* to lie within the range of 101–126 eggs.

The mean hatching success of loggerhead eggs in the area (i.e., 66.4% in 1999; and 76.21% in 2000) was similar to that of 79.1% reported from southern Cyprus, and 67.7% reported from Zakynthos, Greece (Peters and Verhoeven 1992). Overall, the nesting and survival statistics for loggerhead hatchlings from the Egyptian Sinai coast are comparable to other populations found elsewhere in the eastern Mediterranean. Because of the very small number of green turtle eggs found, no meaningful conclusions on hatching success or mean clutch size can be drawn at this time.

Acknowledgments.—This project was supported by a grant from the British government administered through the *Darwin Initiative for the Survival of Species* program. Many thanks to the Egyptian survey team and Dr. Samir Ghoneim for their invaluable help with this work. Appreciation is also extended to Mr. Mohamed I. M. Ibrahim and the staff of the EEAA office in Cairo for their help with obtaining permits. We are indebted to many individuals and organizations which have helped with this project, including Anna Baker and Martin Daltry of the British Council, Peter Hayward of the National Oil Spill Contingency Plan, The Egyptian Coast Guard, the Regional Activity Centre for Specially Protected Areas (SPA/RAC) of the Mediterranean Action Plan (MAP), Shell Egypt, WSPA and Amoco Egypt. Special appreciation is reserved for James Kennedy and all at ENI/Agip Egypt for their very generous support of this project.

Lachesis muta rhombeata Wied, 1825 (Serpentes, Viperidae): Defensive Behavior and Snakebite Risk

ANTÔNIO JORGE SUZART ARGÔLO

Departamento de Ciências Biológicas, Universidade Estadual de Santa Cruz Km 16 Rodovia Ilhéus-Itabuna, CEP 45650-000, Ilhéus, Bahia, Brazil

e-mail: lachesis@uesc.br

Bushmasters (genus *Lachesis*) are remarkable for their large size (≥ 2.0 m total length), venom capacity, and reputation for aggressiveness, which makes them one of the most feared snakes of the New World (Campbell and Lamar 1989; Greene 1997; Hardy and Silva Haad 1998). Their restricted habitat makes the collection of specimens difficult (but see exception in Taylor et al. 1974) and limits studies on the basic aspects of their biology (but see Boyer et al. 1989; Boyer et al. 1995; Chiszar et al. 1989; Melgarejo and Cunha 1991; Ripa 1994, for data on reproduction, captive maintenance and behavior). Another difficulty in collecting specimens for serum production is that many potential collectors fear these snakes. Encounters with bushmasters in their natural habitats are rare, and much popular lore stems from a distorted view of the rural workers who invariably are frightened in these situations. The lack of careful observations leaves unclear the effective risk of snakebites from bushmasters. Indeed, in Brazil, for example, it is said that the low number of accidents caused by this species is probably due to the fact that it is confined to the forests, where human presence is less frequent. In this paper, I present data on the capture of one of the most threatened and lesser known forms of the genus, *Lachesis muta rhombeata* (probably identical to the Amazonian form [Zamudio and Greene 1997]).

Seventy specimens of *Lachesis* were collected from different localities in southeastern Bahia, Brazil, from 1988 to 1998. The specimens are housed in the "Coleção Zoológica Gregório Bondar (CZGB)" of the Centro de Pesquisas do Cacau (CEPEC/CEPLAC), Ilhéus, BA, Brazil, or in captivity at the same institution.

Captures were carried out in a strip of ca. 70 km between the Atlantic coast and 40°20'W and 13°12'S and 16°16'S. Vegetation consists of remnant Atlantic rainforest and cocoa groves (*Theobroma cacao*), pastures, and plantations of rubber and palm oil trees. Some specimens (N = 19; 27.1%) were captured in forest, but the majority (N = 41; 58.6%) were found in cocoa groves. In southeastern Bahia, cocoa is traditionally cultivated under the shade of the forest in a system locally called "cabruca." This fact and the presence of Atlantic forest remnants between the plantations allows the occurrence of a typical forest snake fauna (Argôlo 2001).

The majority of the 70 individuals of *L. m. rhombeata* collected were found coiled on the ground, either exposed or under herbaceous vegetation. From 26 collections for which I have data on activity and behavior, 19 specimens were found between 0700 h and 1530 h, coiled on the ground and apparently asleep. Only 3 of these specimens displayed defensive reactions when approached by the collector. One adult (CZGB 3031) struck the rural worker's machete when he approached the snake without having seen it, inside a cocoa grove. In the same environment, a young specimen (CZGB 1741), after being disturbed, struck the collector. A third specimen (CZGB 7431) coiled in defensive posture and vibrated the tail for a short time before being killed by the collector. These are the only reports of defensive reactions during the captures where circumstances were precisely determined. On the other hand, among several specimens collected under vegetation during cleaning of cocoa groves, one individual was almost stepped on by a rural worker, whereas two others (CZGB 3026, 5599) were stepped on without displaying any reaction. One specimen (CZGB 3316), after being discovered, remained coiled and immobile for five hours while workers removed the vegetation in the vicinity waiting for a collector. None of the five specimens found active (from 1600 to 0600 h) displayed any defensive reactions. One of these (CZGB 3971) was killed at 0100 h inside a house in the field, after having crawled on the body of the sleeping collector. Another specimen, now in captivity at CEPLAC (number B-105), was captured at 2000 h when crossing a road in the vicinity of a forest in Ilhéus. The collector erroneously identified it as the locally common *Boa constrictor* and, relying on illumination only from his car's headlights, attempted to capture it by pulling it by its tail. I collected two specimens (B227, B232) from armadillo caves inside a forest on the Califórnia farm (Ituberá: 13°46'S, 39°12'W). The resident armadillos were not observed, but they likely were *Dasypus novemcinctus*. These caves have one or more inclined entrances ca. 20 cm in diameter each. The ceilings in these caves are dome shaped, smooth, and approximate the size of the armadillo (Emmons, 1999; pers. obs.). As I searched the caves with a flexible stick, the snakes arose immediately through the opening. One of these stopped after flash photography and returned to the interior of the cave. The second specimen, also stimulated to exit the cave, was found shedding its skin. It coiled near the entrance to the cave and I was able to capture it by hook and a tail hold. None of these

specimens showed any defensive reaction during the captures.

Published summaries of human envenomations suggest that snakebites by species of *Lachesis* are infrequent (Hardy and Silva Haad 1998; Jorge et al. 1997). Envenomings attributed specifically to southeastern Bahia are also rare; among 625 venomous snakebites attended at hospitals in Ilhéus and Itabuna in four years, only three could be attributed to *Lachesis* (Argôlo et al. 1998). In a general sense, there is a tendency in Brazil to attribute the low frequency of bites from bushmasters to the fact that this snake is confined to forests, where contact with humans is minimized. However, this species is relatively common in some cocoa groves in southeastern Bahia, yet accidents are still rare.

Acknowledgments.—Specimens of *Lachesis* and information regarding field encounters were provided by Fernando (deceased) and Cristinalvo Gally, José Pereira, Nivaldo de Jesus, Márcio Oliveira, and Roque Magalhães. I thank Miguel T. Rodrigues for critical reading of the manuscript, and Janisete Gomes da Silva and Carter Miller for help in translating the manuscript into English.

Boulengerula fischeri Nussbaum and Hinkel, 1994 is an Objective Junior Synonym and a Homonym of *Boulengerula fischeri* Nussbaum and Hinkel *in* Fischer and Hinkel, 1992 (Amphibia, Gymnophiona)

STEFAN LÖTTERS
Institute of Zoology, Ecology Department, University of Mainz
Saarstrasse 21, 55099 Mainz, Germany
e-mail: stefan@oekologie.biologie.uni-mainz.de

The gymnophione species *Boulengerula fischeri* Nussbaum and Hinkel, 1994 was named in honor of the donor (E. Fischer), based on a single individual collected by him in Cyagugu Prefecture, Rwanda. While this species description was in progress, Fischer and Hinkel (1992) published a monograph on Rwanda's flora and fauna. They (p. 105) referred to the new gymnophione species as: "*Boulengerula fischeri* Nussbaum and Hinkel in press." In addition, some diagnostic characters were provided plus a color photograph (p. 115) of the single known specimen (i.e., the later holotype of Nussbaum and Hinkel 1994). Although it was not the authors' intention, the description published in Fischer and Hinkel (1992) is valid under the International Code of Zoological Nomenclature (International Commission on Zoological Nomenclature 1999). Accordingly, *Boulengerula fischeri* Nussbaum and Hinkel, 1994:756 has to be treated as an objective synonym and a homonym of *Boulengerula fischeri* Nussbaum and Hinkel *in* Fischer and Hinkel 1992:105.

Tail Loss in Garter Snakes

HENRY S. FITCH
Fitch Natural History Reservation, 2060 East 1600 Road
Lawrence, Kansas 66044, USA

Tail autotomy is part of the defensive strategy of the common garter snake (*Thamnophis sirtalis*), with the greatest frequency in adult females because their mass facilitates breakage. If garter snakes are held by the tail, they rotate the body with a whirling motion that quickly gains momentum and snaps off the tail (Fitch 1965, 1999). In the present report I explore further the topic of tail breakage in garter snakes, comparing the incidence of breaks in the sexes, and in adults vs. young (Tables 1–4).

Methods and Materials.— The records used in this study were gathered during the course of ecological studies on the Fitch Natural History Reservation (FNHR). Only records obtained during the decade of the 1990's (1828 in all) were used. The ratio of those with tail breaks vs. those with intact tails is noted. Two sets of figures were used and compared. In the larger set every capture was included, with the result that some individuals, those recaptured several times, were overrepresented. In the second sample each individual was tallied only once—at its first capture. However, this data set excluded many records of older snakes that were most likely to have broken tails. On a few occasions I accidentally broke a tail in handling a snake, but the vast majority of breaks are believed to have resulted from the attacks of natural predators such as the coyote (*Canis latrans*), striped skunk (*Mephitis mephitis*), raccoon (*Procyon lotor*), opossum (*Didelphis virginiana*), red-tailed hawk (*Buteo jamaicensis*), and great blue heron (*Ardea herodias*). In the tables, males of 400 mm or more SVL were listed as mature, as were females of 500 mm or more.

Results and Discussion.—When a tail breaks, the broken end is very active, performing a series of lateral contractions which may be so rapid that it is seen as a blur, causing it to skip and hop about on the surface of the ground. The lively movements of the detached tail may distract the attention of a predator momentarily, permitting the snake to escape, and the large number of snakes having part of the tail missing suggests the success of the strategy. By sacrificing part of the tail, garter snakes sometimes save their own lives, but it seems that some handicapping may result. Garter snakes with stub tails are noticeably slower in swimming or crawling, and the greater the length of lost tail the more serious the disadvantage. Cooper and Alfieri (1993) described tail autotomy in *T. s. sirtalis* of Seabrook Island, South Carolina and emphasized the greater activity of adults in twisting off the tail; the only small juvenile which they observed did not attempt to autotomize when handled. However, when picked up by the tail, juveniles as well as adults may perform the whirling movements that can result in autotomy. The response tends to be weaker in juveniles than in adults, and is much less effective because of their smaller mass. Unlike lizards, snakes do not regenerate broken tails.

Tail breaks may often result from attempted predation, unsuccessful in all recorded cases, since the snake had survived. Some parts of the tail seem to be more fragile, or else they are more liable to be targeted by predators. In my sample there were no tail breaks from the end of the body to about the seventeenth percentile. The remainder of the tail break lengths were not randomly distributed. In female snakes there was a concentration of breaks at about one-fourth of the distance to the tip, with 17.2% of the sample between the 20th and 29th percentile. Ninety snakes (27.95%) were missing their tail tips, and this was the most frequent type of tail injury. In males, breaks across the tail base would damage the hemipenes. Males average smaller than females but have relatively longer tails. In courtship the male's tail serves a tactile function, helping to bring the vents of male and female together (Fitch 1999), and presumably loss of any of the tail would interfere with male courtship. The increased survival gained by tail autotomy presumably outweighs these handicaps (Fitch 1999). The number of damaged tails in a population obviously depends on the kinds and numbers of snake-predators that are present, as well as the amount, quality, and distribution of escape cover. There-

TABLE 1. Tail breakage compared in adult and juvenile red-sided garter snakes, first captures only.

	Intact Tails	Broken Tails	Totals
Adults	764	122	886
Juveniles	441	11	452
Totals	1205	133	1338

chi-square = 42.95, P = 0.001

TABLE 2. Tail breakage compared in adult male and female red-sided garter snakes, first captures only.

	Intact Tails	Broken Tails	Totals
Males	358	41	399
Females	406	81	487
Totals	764	122	886

chi-square = 7.40, P = 0.005

TABLE 3. Tail breakage compared in adult and juvenile red-sided garter snakes, including all recaptures.

	Intact Tails	Broken Tails	Totals
Adults	982	257	1239
Juveniles	551	38	589
Totals	1533	295	1828

chi-square = 10.63, P = 0.0001

TABLE 4. Tail breakage compared in adult male and female red-sided garter snakes, including all recaptures.

	Intact Tails	Broken Tails	Totals
Males	521	107	628
Females	461	150	611
Totals	982	257	1239

chi-square = 60.24, P = 0.0001

fore, the incidence of breakage could be expected to differ at each locality, and to change over time.

In the data set that included recaptures, snakes probably averaged older and therefore had a higher ratio of broken tails, but the trends for the two data sets are similar. In both samples, females had higher frequencies of broken tails than males, and adults had higher frequencies of broken tails than juveniles (Tables 1–4). Tail breaks are not common in first-year snakes, and it seems that immatures seldom rely on autotomy for defense. Of first-year young (less than 350 mm SVL) only 2.42% of 452 had broken tails, but for 886 larger snakes the ratio was 13.7%. As adult size is attained the incidence of tail breaks rises sharply, especially in females. The incidence of breakage was 10.3% in 399 males and 16.7% in 487 females. It is not known how much tail loss affects survivorship.

Acknowledgments.—I thank my daughter, Alice F. Echelle, and Galen L. Pittman for advice concerning statistics.

Using Rims to Hinder Amphibian Escape from Pitfall Traps

MARC J. MAZEROLLE
*Centre de Recherche en Biologie Forestière, Pavillon Abitibi-Price
Université Laval, Québec, Québec G1K 7P4 Canada
e-mail: marc-j.mazerolle.1@agora.ulaval.ca*

Pitfall traps, either arranged in grids or associated with drift fences, are commonly used to assess amphibian species richness and abundance in various habitats (Corn 1994). However, trap efficiency is believed to differ across species, as some species are more likely to be captured and remain in traps than others (e.g., tree frogs can climb out, large individuals may jump out; Corn 1994). This is particularly important in large-scale studies with distant sites or large numbers of traps that cannot be checked daily (e.g., Bury and Corn 1987; Degraaf and Rudis 1990; deMaynadier and Hunter 1998; Mazerolle 2001; McLeod and Gates 1998; Stockwell and Hunter 1989). To overcome this problem, researchers have made different modifications to traps, such as varying trap size (Vogt and Hine 1982), or adding funnels (Corn 1994; Vogt and Hine 1982), side flaps (Nadorozny and Barr 1997), pivoting top flaps (Christiansen and Vandewalle 2000), or rims (Bury and Corn 1987; Stenhouse 1985). However, very few investigators have experimentally tested the effectiveness of their alterations against amphibian escape (but see Brown 1997; Christiansen and Vandewalle 2000; and Vogt and Hine 1982). In this paper, I present data collected in field conditions to test the effectiveness of pitfalls with and without rims in hindering amphibian escape (i.e., animals being missing from the trap).

All experimental trials were conducted in Rankin Bog (46°48'N, 65°00'W), a peat bog within Kouchibouguac National Park, in southeastern New Brunswick, Canada, during the summers of 1998, 1999, and 2001. Pitfall traps consisted of 11.4-L plastic buckets (24 cm diameter x 30 cm height), each of which was placed in a shallow hole ca. 10 cm in depth. This ensured that the tops of the buckets were well above the bog surface to alleviate the probability of an accidental capture during trials. Each trap was a quarter-filled with water, and a thick mat of *Sphagnum* moss was added in the buckets to provide cover (Mazerolle 2001). Rims were fashioned from bucket lids by cutting out their center portion, leaving a margin of 2 cm. These rims were added to some traps to test whether the presence of rims helps prevent escapes from the pitfall traps.

A predator exclosure was built around the entire array of buckets in 2001 to test whether escape rates were confounded with avian or mammal predation at the site during 1998 and 1999. The exclosure (0.91 m in height and 7.2 m in circumference) consisted of plastic snow fencing with a mesh size of 1 cm^2. The top of the exclosure was covered with nylon window screening fastened with clothespins to hinder avian predation.

I collected individuals of five amphibian species (see Table 1) from breeding ponds in the proximity of Kouchibouguac National Park. Amphibians also were collected during night driving surveys conducted on rainy evenings (Shaffer and Juterbock 1994) between April and September of 1998, 1999, and 2001 in the same area. Individuals were temporarily housed in a cool dark room and used in experimental trials within 36 h of capture. At the beginning of experiments, I measured the snout–vent length (SVL) of each amphibian. Individuals were randomly allocated to buckets fitted with or without rims, with the restriction of a single individual to each bucket. During a given trial period, the number of traps employed varied depending on the number of amphibians at hand (range 5–27 traps); for each species, half the individuals were randomly allocated to traps with rims, with the other half assigned to traps without rims. In those cases with an odd number of amphibians, the last individual was randomly allocated to one of the two trap types. The traps were arranged in a small grid of ca. 5 m^2. Traps were checked four days following the introduction of amphibians to assess whether animals were present or absent. Each individual was used only once, and was released at its original capture location if it was present in the trap at the end of the trial. A total of 256 individuals was tested over 17 four-day periods during 1998, 1999, and 2001.

I used logistic regression (Hosmer and Lemeshow 1989) to assess, for each species placed in pitfall traps, the effect of trap type (i.e., with or without rim) on the probability of being missing from the trap at the end of the trial. I accounted for the presence or absence of a predator exclosure by systematically including the variable in all models. Snout–vent length (SVL) was added to models if it was significant at $\alpha = 0.10$ in univariate logistic regressions (Type III log-likelihood ratio statistic, SAS Institute Inc.

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother 2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. SSAR Herpetol. Circ. 29:1–82; for Mexico as it appears in Liner 1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*. Herpetol. Circ. 23:1–113), LOCALITY (use metric for distances and give precise locality data), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author—curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Leviton et al. 1985, *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology*, Copeia 1985[3]:802–832) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief), SUBMITTED BY (give name and address in full—spell out state names—no abbreviations).

Some further comments. This geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens which have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality color slide or photograph may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Color slides and photographs *must* be deposited in a university or museum collection along with complete locality data, and the color slide catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary) to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extensions unless a thorough literature review has been completed.

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **Alan M. Richmond** (USA & Canadian records only); **Jerry D. Johnson** (Mexico and Central America, including the Caribbean islands); **Hidetoshi Ota** (all Old World records); or **Gustavo J. Scrocchi** (South American records). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments. Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Marques, O. A. V., and G. Puorto. 1996. Geographic Distribution. *Chironius laevicollis*. Herpetol. Rev. 27:212.

CAUDATA

AMBYSTOMA OPACUM (Marbled Salamander). USA: VIRGINIA: Scott Co: Rikemo Lodge, ca. 1 km SW of Dungannon. 8 May 1999. Christopher S. Hobson, Steven M. Roble, Anne C. Chazal. Verified by Richard Hoffmann. Virginia Museum of Natural History (VMNH) 10337. Sub-adult found in a small pit (ca. 0.25 m deep) covered by a piece of plywood at Rikemo Lodge, situated on a slope just above the floodplain of the Clinch River. First record for Scott Co., and first published record for southwestern Virginia (Mitchell and Reay 1999. Atlas of Amphibians and Reptiles in Virginia. Spec. Publ. No. 1, Virginia Department of Game and Inland Fisheries, Richmond, Virginia. 122 pp.; Tobey 1985. Virginia's Amphibians and Reptiles: A Distributional Survey, Virginia Herpetological Survey, Purcellville, Virginia, 113 pp.). The nearest published records within the Ridge and Valley physiographic province are from Knox County, Tennessee (ca. 160 km SW), and Montgomery County, Virginia (ca. 180 km NE) (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, Center for Field Biology, Austin Peay State University, 94 pp.; Tobey 1985, *op. cit.*). This record partially fills a hiatus in the known range for this species that includes much of the southern Appalachians; northeastern Kentucky and Tennessee, western North Carolina, and southwestern Virginia (Conant and Collins 1991. Reptiles and Amphibians of Eastern/Central North America. Houghton Mifflin Co., Boston, Massachusetts, 450 pp.).

Submitted by **CHRISTOPHER S. HOBSON** (e-mail cshobson@dcr.state.va.us) and **STEVEN M. ROBLE** (e-mail: sroble@dcr.state.va.us), Virginia Department of Conservation and Recreation, Division of Natural Heritage, 217 Governor Street, Richmond, Virginia 23219, USA.

AMBYSTOMA MACRODACTYLUM (Long-Toed Salamander). USA: CALIFORNIA: Tehama Co: Lassen National Forest, Cascade Range, Carter Meadow (40°1324.78"N, 121°24'43.76"W) 1860 m elev. 5 August 2002. Chris R. Feldman and Daniel G. Mulcahy. CAS 225059–60. Verified by Jens Vindum. New county record (Vindum and Koo 2002, Amphibians and Reptiles of the Lassen National Forest: Results of 02-CS011050650-029, the 2002 California Academy of Sciences Survey). The nearest known localities are: 18.5 km S (Coon Hollow, Butte Colorado; MVZ 60909), 12.6 km E (6.4 km SW of Chester, Plumas Co.; MVZ 50204), and 18.3 km N (Bunchgrass Creek, Plumas Co.; CAS 225057). We found the two adult salamanders inside decaying logs in a closed canopy portion of the meadow. In northeastern California, *A. macrodactylum* occurs in mid-elevation meadows, ponds, and lakes. Such habitat is common in the northern Sierra Nevada and southern Cascade Mountains, and *A. macrodactylum* is likely contiguous throughout this region.

We thank Michelle Koo, Jens Vindum, Melanie McFarland, and Ken Roby for supervision during field surveys, which were funded by Challenge Cost-Share Agreement #02-CS-11050650–029, Forest Service Region 5, Lassen National Forest.

Submitted by **CHRIS R. FELDMAN** (e-mail: elgaria@biology.usu.edu) and **DANIEL G. MULCAHY** (e-mail: dmulcahy@biology.usu.edu), Department Biology, Utah State University, Logan, Utah 84322-5305, USA.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander). USA: TENNESSEE: Sullivan Co: South Holston Weir Dam, 50 m E of intersection of Holston View Dam Road and TVA Road South (36.5218N, 82.1064W). 7 March 2002. Kevin Hamed and Phil Gentry. Verified by A. Floyd Scott, Austin Peay State University Museum of Zoology, APSU 3344. First record from Sullivan County and second record from upper East Tennessee (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ.

No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp.).

Submitted by **M. KEVIN HAMED**, Steele Creek Park Nature Center, P.O. Box 1189, Bristol, Tennessee 37620, USA. (e-mail: khamed@bristoltn.org), and **PHILLIP D. GENTRY**, Tennessee High School, 1112 Edgemont Ave, Bristol, Tennessee 37620, USA (e-mail: gentryp@btcs.org).

ANURA

BUFO MARINUS (Cane Toad). COSTA RICA: PUNTARENAS: Amistad Biosphere Reserve (8°59'N, 82°49'W), ca. 2200 m elev.: On a small hilltop along the trail leading from the Las Alturas de Cotón field station to Cerro Burú and Cerro Echandí. 14 July 2002. M. A. Schlaepfer and K. A. Pilgrim. KU Photograph Collection (CT 11890–891). Verified by Jay M. Savage. New elevational record for this species, which is generally not found above 1600 m in Costa Rica (Savage 2002. The Amphibians and Reptiles of Costa Rica. University of Chicago Press, Chicago, i–xx + 934 pp.). Campbell (1999. *In* W. E. Duellman [ed.], Patterns of Distribution of Amphibians: A Global Perspective, pp. 111–210. Johns Hopkins Univ. Press) indicated that this species should occur as high as 2000 m elev. in the highlands of Middle America. The specimen reported herein was found in primary lower montane rainforest in an area with no apparent evidence of standing water necessary for breeding. This record may have important implications in the ability of *B. marinus* to expand its range into higher and cooler regions of the world.

Submitted by **MARTIN A. SCHLAEPFER**, Neurobiology and Behavior, Mudd Hall, Cornell University, Ithaca, New York 14853–2702, USA (e-mail: mas50@cornell.edu), and **KERI A. PILGRIM**, Department of Biological Sciences, G–419 Lilly Hall, Purdue University, West Lafayette, Indiana 47907–1392, USA.

BUFO QUADRIPORCATUS (Four-Ridged Toad). BRUNEI: TUTONG DISTRICT: Sungai Ratuan Uluh, slow–flowing stream through peat swamp forest, ca. 200 m behind Pangkalan Kubo at Tasik Merimbun (04°4'52.9"N, 115°1"24.4"E; pH 3.9). 15–18 May 1996. Heok Hui Tan. Raffles Museum of Biodiversity Research: Zoological Reference Collection (ZRC.1.4376, one subadult, SVL 15.3 mm, exhibiting characteristic elongate paratoids; ZRC.1.4377–4378, two larvae, Gosner stages 38 and 40, total lengths 16.4 mm and 16.7 mm, respectively; both larvae exhibiting diagnostic labial tooth row formula of 2(2)/3 (Leong and Chou 1999. Raffles Bull. Zool. 47[1]:81–137). Verified by Kelvin K. P. Lim. New country record, in addition to Sabah, Sarawak, and Kalimantan, confirming its postulated occurrence in Brunei (Inger and Stuebing 1997. A Field Guide to the Frogs of Borneo. Natural History Publications, Kota Kinabalu, Sabah, Malaysia. ix + 205 pp.). This represents the fourth species of the genus *Bufo* recorded from Brunei (Das 1995. Raffles Bull. Zool. 43[1]:157–180).

Submitted by **TZI MING LEONG** (e-mail: scip0132@nus.edu.sg) and **HEOK HUI TAN** (e-mail: betta@singnet.com.sg), Systematics and Ecology Lab, Department of Biological Sciences, National University of Singapore, Singapore 119260.

BUFO VALLICEPS (Gulf Coast Toad). EL SALVADOR: AHUACHAPÁN: Parque Nacional El Imposible, La Fincona (13°50.8'N, 89°58.8'W), 720 m elev. 17 June 1997. J. Kreutz and M. Vesely. Forschungsinstitut und Naturmuseum Senckenberg (SMF 81319). Verified by J. R. McCranie and J. R. Mendelson. First record for El Salvador (Mendelson 1998. Sci. Pap. Nat. Hist. Mus. Univ. Kansas 8:1–12). The historical specimens of *Bufo "valliceps"* reported by Mertens (1952. Die Amphibien und Reptilien von El Salvador, auf Grund der Reisen von R. Mertens und A. Zilch. Abh. Senckenb. Naturf. Ges. 487. pp. 1–120) have subsequently been identified as *Bufo leutkenii.*

Submitted by **GUNTHER KÖHLER**, Forschungsinstitut und Naturmuseum Senckenberg, Sektion Herpetologie, Senckenberganlage 25, D–60325 Frankfurt a. M., Germany; e-mail: gkoehler@senckenberg.de.

ELEUTHERODACTYLYS AUGUSTI (Barking Frog). USA: NEW MEXICO: DOÑA ANA CO: Organ Mts., Aguirre Springs Campground, campsite #8; ca. 4.5 air mi SE Organ. 5 Sept. 2001. Ian Murray. Verified by Tomas Giermikowski. MSB 62816. New county record and a range extension of ca. 89 miles to the WNW (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque. 431 pp.).

Submitted by **IAN MURRAY**, 501 Sundown Avenue, Alamogordo, New Mexico 88310, USA, and **CHARLES W. PAINTER,** Endangered Species Program, New Mexico Department of Game and Fish, P.O. Box 25112, Santa Fe, New Mexico 87504, USA.

ELEUTHERODACTYLUS PAULODUTRAI (Paulo's Robber Frog). BRAZIL: BAHIA: Municipality of Salvador, Ondina, Campus da Universidade Federal da Bahia (12°58'S, 38°30'W; 8 m elev.). 24 May 2002. M. F. Napoli. Verified by Ulisses Caramaschi. Museu Nacional, Rio de Janeiro (MNRJ 30410–30411). First record outside the type locality (Centro de Pesquisas do Cacau, Ilhéus, southeastern Bahia, 14°47'S, 39°02'W, 52 m elev.), and northernmost for the species. This new record extends the range ca. 210 km northward. Specimens were collected at night as they called in leaf litter or on stems and small branches standing upright 60 cm from the ground.

Submitted by **MARCELO F. NAPOLI**, Departamento de Zoologia, Instituto de Biologia, Universidade Federal da Bahia, Rua Barão de Geremoabo, Ondina, 40170–290 Salvador, Bahia, Brazil (e-mail: napoli@ufba.br) and **FERNANDA BRANDÃO**, Departamento de Vertebrados, Museu Nacional, Quinta da Boa Vista, Rio de Janeiro, 20940–040 Rio de Janeiro, Brazil.

ELEUTHERODACTYLUS PLANIROSTRIS (Greenhouse Frog). USA: FLORIDA: WAKULLA CO: Panacea, St. Marks National Wildlife Refuge, ca. 0.3 km E of the intersection of St. Marks NWR roads 325 and 316 (30.026°N, 84.410°W). 23 October 2002. Steve A. Johnson, Jennifer S. Staiger, and William J. Barichivich. Florida Museum of Natural History, University of Florida, Gainesville (UF 134605). Verified by Kenneth Löver Krysko. We captured one adult (23 mm SVL) in a funnel trap associated with a drift-fence array (EYR site) on 23 October 2002 and two more adults on 25 October 2002, one in a funnel trap (NAT site) and the other in a pitfall trap (SPC site, UF 134606) at

drift-fence arrays at St Marks NWR (Special Use permit no. 02011). All three arrays were within 1 km of each other and situated in sandhill uplands. Additionally, on 20 September 2002, SAJ heard several *E. planirostris* choruses in wooded areas along the north side of CR 372 east of US 98 at Ochlockonee Bay. These apparently are the first county records for the species (Conant and Collins 1998. Peterson Field Guide to Reptiles and Amphibians of Eastern and Central North America. Third edition expanded. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.). Greenhouse frogs occur in Tallahassee, Florida (Leon Co.), ca. 50 km N of Panacea, and were first documented there in 1963 (Reichard and Stevenson 1964. Florida Nat. 37:97). One individual was recently collected near Carrabelle, Florida (Franklin Co.), ca. 35 km SE of Panacea (Krysko and Reppas 1999. Herpetol. Rev. 30:106).

In late 1977, herpetologists with the U.S. Fish and Wildlife Service initiated intensive herpetofaunal sampling with drift-fence arrays at 14 sites within St. Marks NWR. They trapped continuously for 20 months and did not catch *E. planirostris* at any of the sites (U.S. Fish and Wildlife Service 1980. St. Marks National Wildlife Refuge: Forestry Management and Non-game Wildlife, unpubl. final report, Gainesville, Florida). Using the USFWS's drift-fence array design and sampling at 12 of their 14 sites, we captured the above *E. planirostris* during our first sampling period. Thus, Greenhouse Frogs appear to have colonized the Panacea area within the last 20 years, and our captures are the first records of the species on St. Marks NWR.

Submitted by **STEVE A. JOHNSON**, **JENNIFER S. STAIGER,** and **WILLIAM J. BARICHIVICH**, U.S. Geological Survey, Florida Integrated Science Centers, Center for Aquatic Resources Studies, 7920 NW 71st St., Gainesville, Florida 32653, USA.

HYLA PENTHETER. MÉXICO: MÉXICO: 9 km W El Salitre on road to Nanchititla (100°18'58"N, 18°52'52"W, 1900 m elev.). 19 April 2002. G. Parra-Olea and M. García-París. Colección Nacional de Anfibios y Reptiles, Instituto de Biología, UNAM (IBH13807). Verified by L. Canseco-Márquez. One adult female found under a small stone by a damp road bank covered by liverworts and ferns, at the edge of a relatively dense pine forest. This is the northernmost record for the species and first record for the state of México. It was previously known only from cloud forest at elevations of 1280–2000 m on the Pacific versant of the Sierra Madre del Sur in Guerrero and Oaxaca (Duellman 2001. Hylid Frogs of Middle America, vol. 2, supplement: 963–964, 1129, SSAR Contrib. Herpetol. 18). The habitat for this record differs considerably from previous reports, as it was found in relatively dry pine forest, although remnants of cloud forest are still present nearby.

Submitted by **G. PARRA-OLEA**, **G. CASAS-ANDREU**, Instituto de Biología, UNAM AP 70–153 México, DF 04510, México; **X. AGUILAR-MIGUEL**, CIRB, Facultad de Ciencias, UAEM, Instituto Literario #100, Toluca, Estado de México, México; and **M. GARCIA-PARIS**, Museo Nacional de Ciencias Naturales, CSIC. José Gutiérez Abascal, 2, 28006 Madrid, Spain.

HYLA VERSICOLOR (Gray Treefrog). CANADA: ONTARIO: ALGOMA DISTRICT. Thessalon Twp., 0.8 km N of Hwys 129 and 17 intersection (NAD 27: UTM Zone 17: N5127200m, E304000m). 7 June 1999. Wayne F. Weller. Royal Ontario Museum (ROM 38443 [segment 23], audio cassette tape). All tape recordings and photographs verified by Ross D. MacCulloch. Intense calling from marsh behind homes in rural setting at 2425 h. This record is the westernmost location among 17 others where calls were recorded (ROM 38443 [segments 6 to 22], audio cassette tape), and 9 other locations where calling was noted within 650 km² of the Thessalon/Basswood Lake area. ALGOMA DISTRICT. Tarentorus Twp., N of Kinsman Park, Sault Ste. Marie (NAD 27: UTM Zone 16: N5163800m, E708600m). 14 June 2001. Wayne F. Weller. Royal Ontario Museum (ROM 39374 [segment 19], audio cassette tape). Moderate calling from wetland behind homes in rural setting at 2210 h (air temperature 25°C) under overcast sky. This record is the westernmost location among four others where calls were recorded (ROM 39374 [segments 4, 5, 20, 21], audio cassette tape), and nine other locations where calling was noted within 450 km² of the Sault Ste. Marie area. ALGOMA DISTRICT. Martel Twp., 2.7 km S of Lane and Martel Twp. boundary (NAD 27: UTM Zone 17: N5211600m, E336800m). 12 June 2001. Wayne F. Weller. Royal Ontario Museum (ROM 39374 [segment 16], audio cassette tape). Intense calling from roadside wetland along Hwy 129 at 2300 h (air temperature 15°C). This record is the northernmost location among six others where calls were recorded (ROM 39374 [segments 1–3, 15, 17, 18], audio cassette tape), where one specimen was photographed (ROM 39373), and 11 other locations where calling was noted within 750 km² of the Aubrey Lake area. The documented western range limit in central Ontario is represented by specimens from the Walford/Massey area in extreme southwestern Sudbury District: Sugar Lake area (National Museum of Canada [NMC] 7456 – August 1963); Cameron Falls area (NMC 33487 – August 1990); Massey (NMC 7397, 7452, 7495 – August and September 1963). The 18 documented records from the Thessalon/Basswood Lake area extend the range 100 km W of the Walford/Massey area. The five documented records from the Sault Ste. Marie area extend the range 160 km to the WNW, and the eight documented records from the Aubrey Lake area extend the range 115 km to the NW. Collectively, these 31 documented records represent the first vouchered records for Algoma District in Ontario, and substantiate observations received from several people over the period of 1974–1997 for Algoma District.

Submitted by **WAYNE F. WELLER**, 250 Chercover Drive, Thunder Bay, Ontario P7G 1A2, Canada.

PROCERATOPHRYS MELANOPOGON. BRAZIL: MINAS GERAIS: Municipality of Araponga: Fazenda Neblina, Parque Estadual da Serra do Brigadeiro (20°40'S, 42°31'W). November 1994. R. N. Feio and J. L. Pontes. Museu de Zoologia João Moojen de Oliveira, Universidade Federal de Viçosa (MZUFV 2201–03). Municipality of Lima Duarte: Parque Estadual do Ibitipoca (21°42'S, 43°53'W). November 1987. R. N. Feio. MZUFV 542. All verified by U. Caramaschi and J. P. Pombal, Jr. Published distribution of this species includes the mountains of Serra do Mar and Mantiqueira in the states of Rio de Janeiro and São Paulo, in southeastern Brazil (Izecksohn et al. 1998. Rev. Univ. Rural, sér. Ciênc. Vida, 20[1–2]:37–54). These localities represent the first record for the state of Minas Gerais, and the most inland (Ibitipoca) and northern (Serra do Brigadeiro) records for the species.

RANA CATESBEIANA (American Bullfrog). USA: CALIFORNIA: San Francisco Co: John McLaren Park, ca. 20 m SW of intersection of Bacon Street and Oxford Street (37°43'23.94"N, 122°25'6.3"W, 104 m elev.). 25 March 2000. Craig A. Reading. Verified by J. V. Vindum. California Academy of Sciences (CAS) 214825. Single adult male basking on bank of pond. New county record (Banta and Morafka 1966. Wassman J. Biol. 24:223–238). Larvae of *R. catesbeiana* (CAS 218665) were also collected from the same locality indicating that this is a breeding population. Although observations of this species had been recorded in 1966 by Banta and Morafka, this individual and larvae represent the only catalogued museum specimens of *R. catesbeiana* from San Francisco County.

Submitted by **MELANIE M. PAQUIN**, National Marine Fisheries Service, Conservation Biology Division, Seattle, Washington 98112, USA, and **CRAIG A. READING**, Department of Biology, San Francisco State University, San Francisco, California 94132, USA (e–mail: reading@sfsu.edu).

SCINAX AGILIS. BRAZIL: BAHIA: Municipalidade de Prado (17°20'S, 39°13'W, sea level). S. P. Carvalho e Silva, O. L. Peixoto, C. A. G. Cruz, E. Izecksohn. December 1978. Coleção do Departamento de Zoologia, Universidade Federal do Rio de Janeiro (ZUFRJ 210). Found in leaf axils of bromeliads in a restinga formation. Municipalidade de Mucuri (18°05'S, 39°33'W, sea level). M. R. Gomes, S. P. Carvalho e Silva, R. Schasse. May 1988. ZUFRJ 3500/12. Calling from emerging vegetation over a flat swampy area, where tadpoles probably develop. Verified by E. Izecksohn. Previously known only from a few localities in the State of Espirito Santo where the species occurs in littoral scrub formations (restingas). First state record, extends range ca. 250 km N.

Submitted by **OSWALDO LUIZ PEIXOTO**, Departamento de Biologia Animal, Instituto de Biologia, Universidade Federal Rural do Rio de Janeiro, Seropedica, 23851– 970, Rio de Janeiro, Brazil; **MARCIA DOS REIS GOMES** and **SERGIO P. GRAPTEMYS BARBOURI (Barbour's Map Turtle). USA: FLORIDA: Jefferson County: Wacissa River headwaters, parking area at end of southern extension of CR 59; 30°20'23"N, 83°59'28"W. 30 May 2002. Dale R. Jackson and Bob Walker. Verified by Ghislaine Guyot. Florida Museum of Natural History Herpetology Dept. photographic archive (UF 134682). Adult female (292 mm maximum CL, 252 mm PL, 2.8 kg) observed covering nest at 0930 h, released following photography. Clutch of 12 eggs (mean 13.0 g) salvaged to determine fertility. Three of six eggs hatched in 59–60 days at 31°C (first 17 days at 25–29°C), and five of six in 76–78 days at fluctuating 25–29°C. First documented record for county and Aucilla River drainage, ca. 40 km E of recently documented record in Ochlockonee River (Enge et al. 1996. Herpetol. Rev. 27:150–151).

Long considered to be endemic to the Apalachicola River system, this species is now documented from drainages both to the east (Ochlockonee, Aucilla) and west (Choctawhatchee: Wallace 2000. Florida Sci. 63[Suppl. 1]:43; J. Godwin, in litt.). Whether the newly discovered populations are indigenous or the results of human introduction is problematic. The latter is likely for the Aucilla drainage, as the Wacissa River site (from which only one individual is thus far recorded) is a popular recreational area easily accessible to the public. Nonetheless, Pleistocene fossils from the Suwannee River (Jackson 1975. Herpetologica 31:213–219) suggest a historical distribution that extended east of the modern Apalachicola River drainage.

GRAPTEMYS PSEUDOGEOGRAPHICA (False Map Turtle). USA: IOWA: Allamakee Co: Mississippi River, Upper Mississippi River Wildlife and Fish Refuge. This refuge is adjacent to Crawford Co., Wisconsin. T98N, R6W, Sec. 9; 91°07'W, 43°14'E. 15 November 2002. Robert Hagensick. Northern Illinois University HDW-NIU 1933. Verified by Theresa Wusterbarth. New county record. Although this represents a new county record for Iowa, it could easily be considered as coming from Crawford County, Wisconsin, as this species was collected within 3 km W of the arbitrary border of the Mississippi River as illustrated in the Geological and Natural History Survey Topographic map for Eastman Quadrangle. The species has also been observed at Cold Springs, Crawford County, 2.8 km N of Lynxville, Wisconsin, within the backwaters of the Mississippi River (Christiansen and Bailey 1988. The Lizards and Turtles of Iowa, Iowa Dept. Nat. Resources, 20 pp., revised ed. 1997) and (Casper 1996. Geographic Distributions of the Amphibians and Reptiles of Wisconsin, Milwaukee Public Museum 87 pp.) have shown considerable hybridization between *G. ouachitenisas* and *G. pseudogeographica* in the Mississippi River drainage. Both authors have recognized *G. ouachitenisas* and *G. pseudogeographica* as being subspecies of *G. pseudogeographica*. Crother et al. (2000. SSAR Herpetol. Circ. 29, 82 pp.) consider *G. ouachitensis* and *G. pseudogeographica* as distinct species. All previous localities for Iowa are of a generalized nature only listing the Mississippi River. The Crawford County record fills a gap between Grant County on the south, and Vernon County on the north in Wisconsin.

KINOSTERNON CREASERI (Creaser's Mud Turtle). MÉXICO: YUCATÁN: 8 km on road N Celestún. 23 September 2001. Oswaldo Hernández-Gallegos and C. Ballesteros-Barrera. Verified by John B. Iverson. Colección Nacional de Anfibios y Reptiles, Instituto de Biología, UNAM (IBH-RF 19 a–c Color Slides). Westernmost record for the state of Yucatán, extending the geographic range about 100 km (airline) NW of Santa Elena (Lee 1996. The Amphibians and Reptiles of the Yucatán Peninsula. Cornell Univ. Press, Ithaca, New York, 500 pp.; Buskirk 1997. Chelonian Cons. Biol. 2:415–416). The presence of this species in the northwestern portion of the Yucatán Peninsula refutes the speculation that *K. creaseri* may be unable to survive the drier conditions of that area (Iverson 1988. Herpetol. J. 1:285–291). We thank J. B. Iverson for reading an earlier version of the manuscript.

LACERTILIA

ANOLIS COMPRESSICAUDUS (Escorpioncillo). MEXICO, VERACRUZ: Municipality of Las Choapas, Colonia Nueva Tabasqueña Ejido (17°31.42'W, 94°01'N), elev. 100 m. 17 December 2000. Collected by Fahd Carmona in a remnant of rainforest in the ranch El Milagro (IBH 13987). Verified by Roberto Luna Reyes. This is the first record for the state of Veracruz. Previous reports were from Oaxaca and Chiapas. This record extend the distribution 77 airline km W from El Ocote Chiapas (Álvarez del Toro 1956. Herpetologica 12:3–17).

Submitted by **FAHD H. CARMONA-TORRES**, **ADRIANA J. GONZÁLEZ-HERNÁNDEZ**,* and **VÍCTOR-HUGO REYNOSO**, Colección Nacional de Anfibios y Reptiles. Instituto de Biología, UNAM, Circuito Exterior, Del. Coyoacán, C.P. 04510, AP. 70–153, México, D.F. (e-mail: cfahd@hotmail.com); *Laboratorio de Vertebrados Terrestres, Facultad de Ciencias, UNAM, Circuito Exterior. Del. Coyoacán. C.P. 04510. México, D.F.

BASILISCUS BASILISCUS. VENEZUELA: YARACUY: Río Carabobo, El Diamante, Sierra de Aroa. 13 April 1995. E. Camargo. Museo de la Estación Biológica de Rancho Grande, Maracay, Venezuela (EBRG 3209). Río El Zamuro, Sierra de Aroa. 8 August 1995. R. Rivero (EBRG 3160). Both verified by César R. Molina. First state records. *Basiliscus basiliscus* is known in Venezuela from the states of Falcón, Mérida, Táchira, Trujillo, Zulia, and now from Yaracuy. Mijares-Urrutia and Arends (1993. Herpetol. Rev. 24:157–158) reported this species from Falcón state, without biogeographical comments. These localities, along with the Yaracuy ones, are the easternmost for the species, showing that *B. basiliscus* is widely distributed through rivers in the area northeast of the Andes and west to the Coastal Range. Barrio and Orellana (2001. Herpetol. Rev. 32:56–57) stated that CVULA 3481 was the first state record for Trujillo state, but this was evidently an error as Maturana (1962. Bull. Mus. Comp. Zool. Harvard, 128:1–33) reported the species from Trujillo without museum numbers. Thus, CVULA 3481 is the only known voucher specimen for that state. Another locality given by Maturana (*op. cit.*) is "Valencia, Esperanza." The location of Valencia, Esperanza is unclear, but it is shown as somewhere between the states of Barinas and Portuguesa, although we are unable to locate such a place on available maps. However, an area called Valencia, Esperanza is found in the bio-region called "región llanera" (Barrio 1998. Acta Biol. Venez. 18 [2]:1–93), which is well outside the known range of the species. Additionally, near Valencia in Carabobo state, there is a Quebrada La Esperanza, but this is also well outside the expected range of this species. Therefore, we believe that the "Valencia, Esperanza" locality is an error.

CHAMAELEO CHAPINI. EQUATORIAL GUINEA: PROVINCIA CENTRO SUR: Monte Alén National Park: Monte Alén (1150 m elev.). Adult male (YPM 12638) found in stomach of a *Thelotornis kirtlandi* (YPM 12649) collected on 5 June 2002 from above locality by Jorge de Leon. Verified by Wolfgang Böhme. First country record; previously known from Zaire (de Witte 1964. Am. Mus. Nov. 2192: 1–3) and Gabon (Knoepffler 1967. Biologica Gabonica 3[3]:245–247).

Submitted by **GREGORY J. WATKINS-COLWELL** (e-mail: gregory.watkins-colwell@yale.edu) and **JORGE DE LEON** (e-mail: ornithology.library@yale.edu), Division of Vertebrate Zoology, Yale Peabody Museum of Natural History, 170 Whitney Avenue, P.O. Box 208118, New Haven, Connecticut 06520, USA.

ELGARIA MULTICARINATA (Southern Alligator Lizard) USA: CALIFORNIA: PLUMAS CO.: Grizzly Creek near Elephant Butte. On 5 June 2002 at 1318 h, an adult specimen (118 mm SVL) was captured ca. 1 m from the right bank of Grizzly Creek (639559 N, 4413845 E; NAD 27, Zone 10; 509 m elev.). This specimen (CAS 224773) represents the first known occurrence of this species in Plumas County (Koo and Vindum 1999. Amphibians and Reptiles of the Plumas National Forest: Historical Collections and California Academy of Sciences 1998 and 1999 Surveys. Unpublished report on file, Department of Herpetology, California Academy of Sciences. San Francisco, California). A second adult male specimen (CAS 224774; 136 mm SVL) was captured on 23 June 2002 at 1434 h along unnamed forest road from Rich Bar (0655255 N, 4429492 E; NAD 27, Zone 10; 800 m elev.) near confluence of Clear Creek and Mill Creek. The nearest record (CAS 209667) is located ca. 31.6 km SE in Butte County, thus extending the known distribution of the species. Specimens verified by Michelle Koo.

PODARCIS MURALIS (Common Wall Lizard). USA: OHIO: Cincinnati. *Podarcis muralis* was introduced to urban Cincinnati circa 1950 where it established a population which is still expanding. Deichsel and Gist (2001. Herpetol. Rev. 32:230–232) describe the status as of the year 2000 and conclude from a letter written by the person who released specimens in 1950 the subspecific status as *P. m. muralis*, judging from their origin (Lake Garda, Italy). Ferner (2002. Herpetol. Rev. 33:226) confirms a breeding colony in adjacent Kentucky.

We analyzed blood drawn from the vena caudalis of two adults caught on Eastern Avenue in SE Cincinnati in May 2000 where they were subsequently released. Total DNA was extracted following standard proteinase K and phenol chloroform protocols (Sambrook et al. 1989. Molecular Cloning: A Laboratory Manual. Cold Springs Harbor Laboratory Press, Cold Springs Harbor, New York). A segment of 1039 bp including parts of the cytochrome b gene and the threonin t-RNA gene was amplified by PCR (primers: "sicnt-L" 5'–TTTGGATCCCTGTTAGGCCTCTGTT-3' and "H15906" 5'–GGTTTACAAGACCAGTGCTTT-3') and sequenced (primers "sicnt-L" and "murnum" 5'-AGGCACCTCCATAGTTCACC-3') by MWG-BIOTECH (Ebersberg, Germany) sequencing service. A part of the cyt b gene consisting of 1017 bp was used for analysis. Both sequences were identical. These sequences were compared with homologous regions taken from samples that were analyzed in the course of a comprehensive genetic analysis of the species currently underway

(Schweiger and Mayer, in prep.). The sequences most similar to the sequences of the Cincinnati samples were from individuals collected in a region between the Tyrolian Inn Valley in Austria and the southern border of the Alps near Lake Garda in Italy. This similarity confirms the origin alleged by Deichsel and Gist (*loc. cit.*). However, because a revision of the systematics of *P. muralis* is still in progress, the subspecific status of the Cincinnati specimens remains unresolved as well. Sequences were deposited at GenBank under the accession number AY194855. We thank Daniel Gist for local guidance in Cincinnati.

XANTUSIA VIGILIS (Desert Night Lizard). USA: CALIFORNIA: Tulare Co: Sequoia National Forest, Sierra Nevada Mountains, Big Meadows Campground Unit 1, 0.53 km E of FST 29E05 trailhead via FSR 14S11 (N36°43'3.55" W118°49'46.14") 2317 m elev. 21 July 2002. Chris R. Feldman and Daniel G. Mulcahy. CAS 224956. Verified by Jens Vindum. *Xantusia vigilis* is known from the peripheral areas of the Sierra Nevada, restricted to chaparral, desert scrub, and drier mixed pine and oak woodland habitat. East of the Sierran crest, *X. vigilis* occurs in the Mojave–Great Basin transition zone along the lower slopes of the Sierra Nevada and Owens Valley to ~1800 m elev., north to the vicinity of Bishop (Macey and Papenfuss 1991. *In* C. A. Hall Jr. [ed.], Natural History of the White-Inyo Range, Univ. California Press, Berkeley; Scott et al. 1999. Herpetol. Rev. 30:112). On the western slope of the southernmost Sierra Nevada, west of the Kern River drainage, *X. vigilis* is narrowly restricted to grassland, chaparral, oak and grey pine woodland habitat with exfoliating granite to ~600 m elev. in the Greenhorn Mountains, Kern Co. (Bezy 1967. J. Arizona Acad. Sci. 4[3]:163–167). *Xantusia* is widespread in the region from Lake Isabella eastward to Walker Pass, extending south into Kelso Valley, Walker Basin, and Caliente Canyon. Populations of *Xantusia* follow desert scrub and chaparral habitat along the Kern River drainage into southern Tulare Co., at least as far north as Brin Canyon, 3.2 km N of Fairview to ~1100 m elev. (LACM 129881–2), and to the east on the Kern Plateau, in mostly pinyon-juniper habitat along the South Fork Kern River to the Fish Creek drainage, Tulare Co., to ~2250 m elev. (RWH, unpubl.).

While conducting biotic field surveys in Sequoia National Forest, we (CRF, DGM) found a live *X. vigilis* (CAS 224956) under a small granite boulder ~4 m from Big Meadows Creek at 1945 h. Although a massive granite outcrop is nearby, the immediate habitat consists of high elevation coniferous and riparian vegetation such as Lodgepole Pine, Red Fir and willow. This specimen represents a new record for *X. vigilis* in the interior of the Sierra Nevada. The closest museum record is 55 km to the east, near Independence, Inyo Co. (MVZ 228231). However, the highest mountain divide in the contiguous United States separates our specimen and populations east of the Sierran crest. West of the Sierran crest, the nearest population to our specimen occurs in the interior of the Sierra Nevada, restricted to the Kern River drainage, 92 km to the south (LACM 129881–2). Because we found our specimen in a campground, far from any known population of *X. vigilis*, and in habitat not previously recorded for this species, CAS 224956 may represent an introduction. Additional specimens from this locality and intervening areas could demonstrate whether the Big Meadows area contains an established population of *X. vigilis*. Further, a regional genetic survey of *X. vigilis* might have the power to clarify whether our specimen represents a natural or introduced population of *Xantusia*.

We thank Michelle Koo, Jens Vindum, and Phillip Strand for supervision during field surveys, which were funded by Challenge Cost-Share Agreement #00-CC-11051322-034, Forest Service Region 5, Sequoia National Forest.

ARIZONA ELEGANS ELEGANS (Kansas Glossy Snake). USA:COLORADO: WASHINGTON Co., Highway 61, 2.2 mi. N junction County Road 32 (UTM 0673708, 4435583). 7 September 2002. UNC–MNH Photographs 35–36. Verified by David Chiszar and Hobart M. Smith. First county record (Hammerson 1999. Amphibians and Reptiles of Colorado. Second Ed. Univ. Colorado Press, Niwot. xxvii + 484 pp.).

Submitted by **MIKE ROCHFORD, RON MALECKI,** and **STEPHEN P. MACKESSY**, Department of Biological Sciences, University of Northern Colorado, 501 20th Street, CB 92, Greeley, Colorado 80639–0017, USA; e-mail (SPM): stephen.mackessy@unco.edu.

BOTHROPS LEUCURUS (White–tailed Lancehead). BRAZIL: PERNAMBUCO: Serra dos Cavalos; Parque Ecologico João Vasconcelos Sobrinho; Caruaru (08°18'36–08°30'00"S and 36°10'10"W). 22 April 1998. Antônio Ferreira Matos. Instituto de Biologia, Universidade Federal da Bahia (UFBA1214). Verified by Giuseppe Puorto. Serra dos Cavalos (900 m elev. and 350 ha) is an Atlantic forest remnant localized in a semi–arid region of Pernambuco state. *B. leucurus* was known from Bahia, Sergipe, Alagoas, and Ceara states (Porto and Texeira 1995. Herpetol. Rev. 26:156). First state record, extends known distribution ca. 250 km airline NW in the Brazilian Northeast.

Submitted by **MARCO TÚLLIO LIMA DUARTE**, **MARLIETE SOARES**, **ANTONIO DA SILVA SOUTO**, Departamento de Zoologia, Universidade Federal de Pernambuco, Av. Prof. Nelson Chaves, 1235, 50.670–420. Brazil and **REJANE MARIA LIRA-DA-SILVA**, Instituto de Biologia, Universidade Federal da Bahia, Rua Barão de Geremoabo, s/n CEP: 40170–290 Salvador BA, Brazil (e–mail: duartetullio@bol.com.br).

COLUBER CONSTRICTOR FLAVIVENTRIS (Eastern Yellow-bellied Racer). USA:COLORADO: PHILLIPS Co., County Road 61 at junction County Road 14 (UTM: 0746486, 4490198). 26 August 2002. UNC–MNH Photographs 31–32. Verified by David Chiszar and Hobart M. Smith. First county record (Hammerson 1999. Amphibians and Reptiles of Colorado. Second Ed. Univ. Colorado Press, Niwot. xxvii + 484 pp.).

Submitted by **RON MALECKI, MIKE ROCHFORD, DAVID NEELY,** and **STEPHEN P. MACKESSY**, Department of Biological Sciences, University of Northern Colorado, 501 20th Street, CB 92, Greeley, Colorado 80639–0017, USA (e–mail [spm]: stephen.mackessy@unco.edu).

CROTALUS ATROX (Western Diamond-backed Rattlesnake): USA: ARIZONA: MOHAVE Co: Lake Mead National Recreation Area, Pierce Ferry, ca 100 m from water's edge under a picnic platform, Colorado River, river mile (RM) 280 L: 36°07'N, 114°00'W. 27 April 2000. Wayne L. Peterson. KU CT 11877. Verified by Cecil Schwalbe. First verified record for the upper Lake Mead Region and furthest downstream record in the Grand Canyon Region (an extension of 54.3 RM, 87.4 river km; roughly 69 km land distance). Grater (1981. Snakes, Lizards, and Turtles of the Lake Mead Region. Publ. Southwest Parks and Monuments Association. 47 pp.) and Lowe et al. (1986. The Venomous Reptiles of Arizona. Publ. Arizona Game and Fish Department, Phoenix. 115 pp.) suggest that *C. atrox* has been found only in the southern part of the Lake Mead-Lake Mojave Region. MOHAVE Co: Diamond Creek, RM 225.7 L: 35°46'N, 113°22'W. 19 June 2001. Jock Souter. KU CT 11878. Verified by Joseph T. Collins. Third verified record of *C. atrox* in the Grand Canyon Region. The first record of *C. atrox* for this region (KU Color Slide 11725) was from the same drainage (Brown 2000. Herpetol. Rev. 31:54–55).

Submitted by **NIKOLLE L. BROWN**, 7779 North Leonard, Clovis, California 93611, USA; e-mail: black–catnik@att.net.

CROTALUS SCUTULATUS (Mojave Rattlesnake). USA: ARIZONA: MOHAVE Co: Hualapai Indian Reservation, Quartermaster Point, 0.8 km from the Colorado River: river mile (RM) 260.5 L: 35°58'N, 113°47'W. Summer 1999. Ralph Jones. KU CT 11885. Verified by Cecil R. Schwalbe. First verified record in the Grand Canyon Region. Miller et al. (1982. Amphibians and Reptiles of the Grand Canyon. Publ. Grand Canyon Nat. Hist. Assoc. 114 pp.) suggested that *C. scutulatus* might inhabit the lower end of the canyon, however there were no confirmed records. Grater (1981. Snakes, Lizards, and Turtles of the Lake Mead Region Publ. Southwest Parks and Monuments Association. 47 pp.) mentioned that *C. scutulatus* did not appear common in the Lake Mead Region. Lowe et al. (1986. The Venomous Reptiles of Arizona. Publ. Arizona Game and Fish Department, Phoenix. 115 pp.) show the northern distribution of *C. scutulatus* extending north close to the Colorado River near Peach Springs Canyon (RM 225.7 L) and reaching the Colorado River at Pierce Ferry (RM 280 L), but not found near the Colorado River in the intervening region.

Submitted by **NIKOLLE L. BROWN**, 7779 North Leonard, Clovis, California 93611, USA; e–mail: black–catnik@.att.net.

DENDROASPIS POLYLEPIS (Black Mamba). GUINEA: Télimélé (10°54'00"N, 13°01'60"W), 543 m elev. 1996. M. Cellou Baldé. University of Kansas Museum of Natural History (KU CT 11866). Verified by Van Wallach. Adult collected in the hole of a felled tree. First confirmed country record. Although this species has been suggested to occur in Guinea (Droz 1994, *In* Résumé des communications, Premier congrès herpétologique Franco-Suisse. Société Herpétologique de France, Paris. p. 12; David and Ineich 1999. Dumerilia 3:3–499), no specific locality or museum specimen was listed. The nearest records for this species are ca. 420 km NNW in Senegal (Håkansson and Madsen 1983. J. Herpetol. 17:186–89) and ca. 800 km ESE in Burkina Faso (Spawls and Branch 1995. The Dangerous Snakes of Africa. Ralph Curtis Books, Sanibel Island, Florida. 192 pp.).

Submitted by **ELI GREENBAUM,** Division of Herpetology, Natural History Museum and Biodiversity Research Center, The University of Kansas, 1345 Jayhawk Boulevard, Lawrence, Kansas 66045–7561, USA (e–mail: elig@ku.edu), **M. CELLOU BALDÉ,** Institut Pasteur de Guinée, Bp. 146, Kindia, Guinée (e–mail: celloufr@yahoo.fr), and **JOHN L. CARR,** Department of Biology, The University of Louisiana at Monroe, Monroe, Louisiana 71209, USA (e–mail: carr@ulm.edu).

DIADOPHIS PUNCTATUS (Ringneck Snake). USA: CALIFORNIA: Inyo County: Death Valley National Park, Grapevine Canyon: 0.5 mi. E of Scotty's Castle in thick riparian area 5 m from surface water (37°02'00"N, 117°19'20"W), 1027 m elev. 28 March 2002. Kevin Emmerich and Larry O'Hanlon. Museum of Vertebrate Zoology (MVZ 237182 photo voucher). The snake was moving above ground on top of *Salix* sp. and *Vitis* sp. leaf litter. Coloration was light grey with no ring on neck. Because of National Park Service collecting regulations, a 35mm slide was submitted to MVZ. First record for Inyo County. USA: NEVADA: Esmeralda County: 5 mi. E of Lida (37°26'54"N, 117°28'19"W), 1986 m elev. 15 October 2002. Kevin Emmerich and Laura Cunningham. MVZ 238085. The snake was in a pitfall trap under a *Salix lasiolepis*. Coloration was light grey with no ring on neck. First record for Esmeralda County. Specimens verified by Theodore J. Papenfuss. Based on coloration and absence of a neck ring, both specimens are referrable to *D. p. regalis*. These records represent a western extension of the range of that taxon and suggest that additional populations will be found in the desert mountain ranges of western Nevada and extreme eastern California.

Submitted by **KEVIN EMMERICH** and **LAURA CUNNINGHAM**, P.O. Box 70 Beatty, Nevada 89003, USA; e-mail: lacerta@beattynv.com.

DIADOPHIS PUNCTATUS (Ringneck Snake): USA: CALIFORNIA: San Bernardino County: Clark Mountain, Pachalcka Spring (35°31'05"N, 115°37'49"W, elev. 1384 m). 17 April 2000. Collected by Jonathan Richmond and Dustin Wood. Verified by Tod W. Reeder. SDSNH 68893. Female (221 mm SVL) was found under a small rock near the head of the spring. Coloration in life was light olive-gray and lacked the neck ring that typically characterizes this species. It was on the basis of the first specimen from the Providence Mountains that the putative Pacific coast species *amabilis* was lumped into a single wide-ranging species, *D. punctatus* (Croulet 1965. Herpetologica 21:80). MtDNA sequence data collected from this individual show it to be more closely related to *D. p. regalis* from Portal, Arizona than to other *Diadophis* populations in California (C. Feldman, unpubl. data). Coloration, lack of neck ring, and ventral scale counts (231) are also suggestive of *D. p. regalis*. This locality represents ca. 65 km northern extension from the Providence Mountains.

REGINA SEPTEMVITTATA (Queen Snake). USA: MICHIGAN: OGEMAW Co.: Logan Township: SE corner sec. 3, T22N, R4E, The Woodlands Campground (44°19'35"N,83°55'30"E). 27 August 2002. Kevin Allen. Michigan State University Museum (MSUM 14493). Verified by James Harding. Adult specimen collected 3 m from pond. First county record, possible link between populations in southern Michigan and population found on Bois Blanc Island in the Straits of Mackinaw. Extends known range by ca. 130 km (Harding 1997. Amphibians and Reptiles of the Great Lakes Region. University of Michigan Press, Ann Arbor, Michigan. 378 pp.).

Submitted by **KEVIN ALLEN**, The Woodlands Campground, 318 South Sage Lake Road, Hale, Michigan 48739, USA.

SYMPHIMUS MAYAE (Yucatán White-lipped Snake). MÉXICO: YUCATÁN: Municipality of Tizimín, 4.7 km N, 2.8 km E Calotmul (21°03'57.3"N, 88°08'55.3"W), 10 m elev. 14 July 2002. Colección Herpetológica de la Escuela Nacional de Ciencias Biológicas, I.P.N. (CB 17361). Verified by Edmundo Pérez Ramos. Northernmost record for the state and a range extension of 57 km from the previous record from southwestern Yucatán.

Submitted by **NOEMI MATIAS FERRER** and **SERGIO MURILLO**, Escuela Nacional de Ciencias Biológicas, IPN. Prol. de Carpió y Plan de Ayala, Col. Santo Tomás. Apdo. Postal 42-186, México D.F., C.P. 11340, México (e–mail [SM]: smurilloigu@infosel.net.mx).

SIPHLOPHIS COMPRESSUS (False Coral Snake). VENEZUELA: SUCRE: Península de Paria, 1 km NE Manacal, elev. ca. 800 m. 12 September 2000. H. Kaiser and L. Lee Grismer, La Sierra University (LSUPC–S 3255). Verified by Hussam Zaher. First state record and northernmost for the species in Venezuela, falling into the gap between the Amazonian localities (Roze 1966. La Taxonomia y Zoogeografia de los Ofidios de Venezuela. Ediciones de la Biblioteca, Univ. Central de Venezuela, Caracas, Venezuela. 362 pp.) and Trinidad (Murphy 1997. Amphibians and Reptiles of Trinidad and Tobago. Krieger Publ., Malabar, Florida, 245 pp.). The specimen was found foraging at night at the base of a bush and was photographed and released. The presence of *Siphlophis compressus* in Sucre state was predicted by Rivas and Oliveros (1997 "1998." Mem. Soc. Cienc. Nat. La Salle 147:67–80). In Venezuela, this species shows a typical Amazonian distribution in the states of Amazonas, Bolívar, Monagas (Roze 1966, *op. cit.*), and Delta Amacuro (Rivas and Molina, *in press*. Herpetol. Rev.). This record shows that the species has a more extensive distribution in Venezuela than previously assumed, and it suggests that the southern slopes of the Península de Paria may act as the northern limit for Amazonian amphibian and reptile species. The distribution pattern of *S. compressus* is repeated by other snakes, as expressed by Rivas and La Marca (Herpetol. Rev 32:124). The genus *Tripanurgos* was recently synonymized into *Siphlophis* by Zaher and Prudente (1999. J. Herpetol. 33:698–702).

Submitted by **HINRICH KAISER**, Department of Biology, La Sierra University, Riverside, California 92515, USA (e-mail: hkaiser@lasierra.edu), **CÉSAR L. New Records of Reptiles from the Orinoco Delta, Delta Amacuro State, Venezuela

GILSON RIVAS FUENMAYOR
and
CÉSAR R. MOLINA
Museo de Historia Natural La Salle
Apartado Postal 1930, Caracas 1010-A, Venezuela
e-mail (GRF): anolis30@hotmail.com
e-mail (CRM): washaema@hotmail.com

The state of Delta Amacuro is located in eastern Venezuela, and includes the Orinoco River Delta as well as part of the Serranía of Imataca, a total of 40,200 km^2 (PDVSA 1993). This region is framed inside the Venezuelan Guiana (states of Amazonas, Bolívar, Delta Amacuro, eastern Monagas, and southeastern Sucre) which is part of the Guiana Shield (Gorzula and Señaris 1998). Biogeographically, this area is of interest because it is comprised of three big Venezuelan eco-regions: Lowlands, Guiana, and Amazonia. Delta Amacuro possesses very particular geographic and environmental characteristics which are dictated by the area's complex watershed, predominantly the vast quantity of channels and islands formed by the Orinoco River as it drains to the Caribbean Sea and the Atlantic Ocean. In spite of the biogeographical importance of the region, there are only two publications (Gorzula and Arocha-Piñango 1977; Gorzula and Señaris 1998) that mention some of the reptile species found there.

While reviewing specimens collected from the Orinoco River Delta and deposited in the Museo de Historia Natural La Salle, Caracas (MHNLS), Museo de la Estación Biológica de Rancho Grande, Maracay (EBRG) and Museo de Biología, Universidad Central de Venezuela, Caracas (MBUCV) we discovered several species of reptiles whose distribution in Venezuela is poorly known. By reviewing the information on the data cards we were able to extend the distribution of these species in Venezuela. Specimen identifications were verified by Oswaldo Fuentes.

Testudines

Platemys platycephala (Grooved Sideneck). Municipio Antonio Díaz: caño Winikina (09°11'N, 61°06'W) 1 m elev. February 1993. J. Ayarzagüena. MHNLS 15169. First documented museum record for the Orinoco Delta and easternmost record in Venezuela. *P. platycephala* was mentioned by Pritchard and Trebbau (1984) from the Orinoco Delta (no precise locality) based on a personal communication. In Venezuela this species is known from localities in Amazonas, Bolívar, and Monagas states, in the Guiana region (Pritchard and Trebbau 1984).

Amphisbaenia

Amphisbaena alba (Giant Amphisbaena). Municipio Tucupita: Tucupita (09°03'N, 62°02'W), 15 m elev. 08 September 1951. MBUCV 1324–25. First state record (Donoso-Barros 1968; Avila-Pires 1995; Gorzula and Señaris 1998).

Amphisbaena fuliginosa (Mottled Amphisbaena). Municipio Antonio Díaz: Río Ibaruma, 38 km SE of Curiapo (08°10'N, 60°47'W), 15 m elev. 26 February 1995. V. Martínez. MHNLS

13071. Although this species is widely distributed in South America (Peters and Donoso-Barros 1970) this is the first report from Delta Amacuro.

Lacertilia

Gonatodes albogularis (Yellow-headed Gecko). Municipio Pedernales: Pedernales, 0 m elev. 10 December 2002. Oscar Lasso-Alcalá. MHNLS 16104–16106. The specimens, one male and two females, constitute the first state records, the first record from the Venezuelan Guayana, as well as the easternmost locality for the species (Rivero-Blanco 1979). In Venezuela it is known from the western part of the country and the island of Los Monjes in the Gulf of Venezuela (Esqueda et al. 2001; La Marca and García 1987; Rivero-Blanco 1979) and is widely distributed outside of Venezuela. This record extends the known distribution for the species 900 km NE of the nearest known locality (Esqueda et al. 2001). Pedernales is located just 36 km SW from Trinidad, but the presence of this species there is doubtful and requires verification (Hans E. A. Boos, pers. comm.; see also Murphy 1997). The presence of this species in the Orinoco Delta is perhaps a recent introduction, the byproduct of an active maritime commerce.

Hemidactylus palaichthus (Spiny Gecko). Municipio Antonio Díaz: Burojoida island (09°08'N, 60°39'W), 1 m elev. April 1969. J. Bilbao and A. Alvarado. MHNLS 4636 juvenile, 4638 adult male. First state record (Kluge 1969).

Leposoma percarinatum. Municipio Tucupita: Punta Pescador, Boca del Caño Macareo (09°42'N, 61°46'W), 2 m elev. Date not given. G. Solé and E. León. EBRG 3542, adult female. Collected in a flooded forest. Los Castillos de Guayana (08°31'N, 62°22'W). 50 m elev. 01 January 1965. MBUCV 1576. First records for this unisexual species in Delta Amacuro (Donoso-Barros 1968; Uzzell and Barry 1971; Avila-Pires 1995; Gorzula and Señaris 1998).

Tropidurus umbra umbra (Blue-lipped Tree Lizard). Municipio Antonio Díaz: Río Ibaruma, 38 km SE of Curiapo (08°10'N, 60°47'W), 15 m elev. 26 February 1995. V. Martinez. MHNLS 13090. First state record (Donoso-Barros 1968; Etheridge 1970; Avila-Pires 1995; Gorzula and Señaris 1998).

Uranoscodon superciliosus (Diving Lizard). Municipio Antonio Díaz: Río Ibaruma, 38 km SE of Curiapo (08°10'N, 60°47'W), 15 m elev. 3 March 1995. J. C. Señaris. MHNLS 13096. First state record (Donoso-Barros 1968; Avila-Pires 1995; Gorzula and Señaris 1998).

Serpentes

Typhlops brongersmianus (Worm Snake). Municipio Pedernales: Caño Pedernales, 10 m elev. 7 September 1997. J. Ayarzagüena and J. C. Señaris. MHNLS 13799, adult female. First state record (Dixon and Hendricks 1979). Fig. 129 in Gorzula and Señaris (1998) corresponds to specimen MHNLS 13799, which appears as *T. reticulatus*.

Bothrops atrox (Central America Lancehead). Municipio Antonio Díaz: Río Ibaruma, 38 km SE of Curiapo (08°10'N, 60°47'W), 15 m elev. 23 February 1995. J. C. Señaris. MHNLS 13054, adult female. First state record and northernmost for the species (Campbell and Lamar 1989). Collected in a flooded forest.

Chironius carinatus spixi (Machete). Municipio Antonio Díaz: mouth of the Río Acoima, 5 km S of El Toro (08°29'N, 61°29'W), 5 m elev. 24 November 1993. Collector unknown. MHNLS 12774, adult female. First state record and easternmost for the subspecies (Dixon et al. 1993).

Erythrolamprus aesculapii (False Coral Snake). Municipio Antonio Díaz: Río Ibaruma, 38 km SE of Curiapo (08°10'N, 60°47'W), 15 m elev. 2 March 1995. G. Rivas. MHNLS 13088, adult female. First state record. *E. aesculapii* is distributed in Venezuela through the Venezuelan Guiana, a distribution pattern shown by other Guianan-Amazonian Venezuelan species of reptiles (Rivas and La Marca 2001).

Liophis breviceps. Municipio Antonio Díaz: Río Ibaruma, 38 km SE of Curiapo (08°10'N, 60°47'W), 15 m elev. 3 March 1995. R. Figuera. MHNLS 13087, subadult female. Collected in a small well of water. First state record and northernmost for the species in South America (Dixon 1983a).

Liophis reginae reginae. Municipio Pedernales: Caño Pedernales, village of Guacajara, 1 m elev. 15 September 1996. J. C. Señaris. MHNLS 13531, adult male. First country record and westernmost for the subspecies. According to Dixon (1983b) *L. r. zweifeli* intergrades with *L. r. reginae* in Guyana. MHNLS 13531 corresponds to the description of *L. r. reginae*. In Venezuela two other subspecies, *L. r. zweifeli* and *L. r. semilineata* have been reported, the latter mentioned erroneously for Venezuela without voucher specimens (Kornacker 1999).

Siphlophis compressus (False Coral Snake). Municipio Antonio Díaz: Caño Winikina (09°11'N, 61°06'W) 1 m elev. 6 February 1995. V. Ponte and W. Wilbert. MHNLS 13139, adult male. First state record and northernmost in Venezuela (Roze 1966). Stomach contents of this specimen included tails from two geckos (*Gonatodes* sp.). This species feeds exclusively on small lizards (Martins and Oliveira 1998).

Acknowledgments.—We thank Enrique La Marca and Hans E. A. Boos for critiques and suggestions on the manuscript.

The Introduced Brown Anole (*Anolis sagrei*) Occurs in Every County in Peninsular Florida

TODD S. CAMPBELL
Institute for Biological Invasions
Department of Ecology and Evolutionary Biology
569 Dabney Hall, University of Tennessee, Knoxville, Tennessee 37996, USA
e-mail: lizardman@utk.edu

The brown anole (*Anolis sagrei* Dumeril and Bibron 1837), a native of Cuba, the Bahamas, and their satellite islands (Williams 1969), was introduced to at least six different locations in south Florida (USA) in the 1940s (Lee 1985). Since then, this species has rapidly spread northward along the peninsula (Godley et al. 1981) and isolated populations have become established in the Florida Panhandle (Means 1990), Georgia (Campbell 1996; Campbell and Hammontree 1995; Echternacht et al. 1995), Louisiana (Platt and Fontenot 1994), Texas (Dixon 1987), Hawaii (Goldberg and Bursey 2000), Taiwan (Norval et al. 2002), and Grenada, West Indies (Greene et al. 2002). Along with expanding its range by simple diffusion, this species also spreads via jump-dispersal by riding on potted ornamental plants and vehicles (Campbell 1996). Its geographic expansion is best described as stratified diffusion (Shigesada and Kawasaki 1997), roughly analogous to an advancing forest fire that continually releases burning embers, igniting distant spot-fires which eventually coalesce with each other and with the main fire.

Here I document nine new county records for *A. sagrei* in peninsular and northeast Florida (Godley et al. 1981; Campbell 1996; Campbell and Hammontree 1995). This verifies its presence in all 45 peninsular Florida counties southeast of the Suwannee River, and increases to 52 the total number of Florida counties in which this species is established (as of October 2002). Specimens were deposited in the Florida Museum of Natural History Collection (UF) in Gainesville, Florida, and identifications were verified by Kenneth L. Krysko.

Bradford County: KOA Campground on US 301 ca. 1.6 km S of its intersection with SR 100 in Starke. 3 September 2002. Todd S. Campbell. UF 134179–84. Two males and four females collected from a well-established, dense population inhabiting native trees, exotic plants, and landscaping structures throughout the campground.

Desoto County: Morgan Park, ca. 2 km E of Arcadia and ca. 0.5 km N of SR 70 on the east shore of the Peace River. 18 August 2002. Todd S. Campbell. UF 134141–45. One male and four females collected from a well-established, dense population inhabiting a strip of bottomland hardwood hammock habitat between the park entrance road and the Peace River.

Dixie County: Public boat ramp at the end of 8th Avenue in Horseshoe Beach. 1 September 2002. Todd S. Campbell, Kenneth L. Krysko, and Coleman Sheehy, III. UF 134185–86. One male and female collected from large rip-rap boulders used to stabilize the boat ramp. Abundant on trees and fence posts throughout Horseshoe Beach.

Hendry County: Riddle Field, a public park on US 27 in Clewiston. 16 August 2002. Todd S. Campbell. UF 34116–18. Two males and one female collected from a well-established, dense population inhabiting native and exotic vegetation and landscaping timbers throughout the park. Sunset/Ford Park on SR 80 at Martin Luther King Drive (SR 731) in La Belle. 22 August 2002. Todd S. Campbell. UF 134114–15. One male and one female collected from a well-established, dense population inhabiting native oaks, pines, and shrubs throughout the park. This species was observed in La Belle in 1991 (A. C. Echternacht, pers. comm.).

Hernando County: Holiday Inn on Cortez Boulevard (SR 50 / US 98) on the west side of its intersection with I–75 ca. 15 km east of Brooksville. 3 September 2002. Todd S. Campbell. UF 134189. One female collected from a well-established, dense population inhabiting exotic and native vegetation throughout a large complex of hotels and restaurants.

Lake County: Ocala National Forest: Alexander Springs State Park. 1 October 1980. C. R. Smith. UF 50726. Original museum data indicates this specimen was collected in Marion County, but Alexander Springs State Park lies over 5 km east of the Marion-Lake County line, entirely within Lake County. This species is now abundant at this facility.

Okeechobee County: Vacant lot east of Freshman Campus on SW

6th Street and SW 2nd Avenue in Okeechobee. 16 August 2002. Todd S. Campbell. UF 134128–30. One male and two females collected from a large, dense population inhabiting native and exotic vegetation in a residential area. Fort Drum Diner at the intersection of US 441 and NE 326 Trail in Fort Drum. 22 August 2002. Todd S. Campbell. UF 134125–27. Two males and one female collected from a large, dense population inhabiting building materials and disturbed, native vegetation around the diner.

Suwannee County: Capital City Bank on US 129 at the intersection of NW Suwannee and NW Jenkins ca. 0.6 km N of US 27 in Branford. 3 September 2002. Todd S. Campbell. UF 134195–99. Three small males and two small females collected from a large, dense population inhabiting newly planted ornamental vegetation around the bank building, in native vegetation in adjacent residences, and in exotic and native vegetation at a small plant nursery across the street.

Union County: Residence at SW quadrant of the intersection of SW 5th Avenue and SW 5th Street in Lake Butler. 3 September 2002. Todd S. Campbell. UF 134200. One female collected from a newly planted, native ornamental shrub near a residence. This likely represents a recent establishment, as only one other female and two hatchlings were observed during two hours of visual surveys throughout Lake Butler.

Acknowledgments.—Thanks to all the people who let me search their properties for lizards, and to Kenney Krysko for providing museum numbers so quickly.

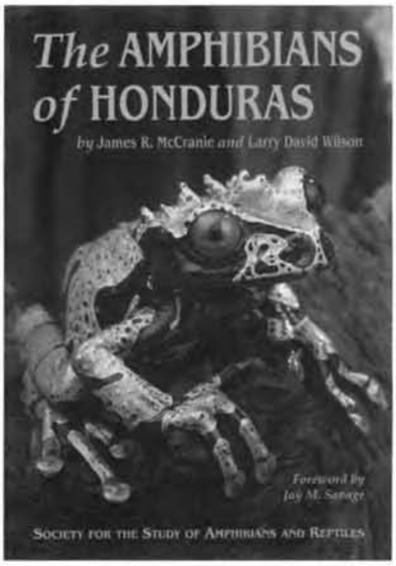
AP 70-153 Ciudad Universitaria, Mexico, D. F. 04510
e-mail: gparra@ibiologia.unam.mx



Honduras is the second largest of the Central American countries. Due to its position in nuclear Central America, with coastlines on the Pacific and Caribbean oceans and a complex interior topography, the Honduran herpetofauna is very rich, consisitng of 333 species: 116 amphibians and 217 reptiles (Wilson and McCranie 2002). Studies of Honduran amphibians date back to the late nineteenth century (Werner 1896), but in general this fauna has received far less attention than that of other Latin American countries. Larry David Wilson began his studies in Honduras in 1967. He and Randy McCranie have been working together since 1976 on the enterprise of documenting and improving our knowledge of Honduran herpetology. This volume is the culmination of almost three decades of their efforts, and an important contribution to Neotropical herpetology.

The Amphibians of Honduras is an exceptional piece of work, with very high quality text and illustrations. As Jay Savage points out in his foreword, this is the first book that is a complete treatment of the amphibians of any Mesoamerican country. The depth and breadth of coverage sets a very high standard for those of us interested in doing similar projects. This book is the result of scholarly work both from the field and the laboratory. Their effort includes 1500 field days (the authors actually collected 94% of the species) and the examination of 9550 adult specimens, 447 tadpole lots, and 43 egg clutches. The authors not only have documented the presence and distribution of various taxa but have also contributed substantially to the systematics of the Honduran fauna, including the description of a new frog genus (*Atelophryniscus*), and descriptions of new species in 42% of the amphibian genera previously known from Honduras (a total of 40 new species). This number is even more striking if we consider that the authors have described 50% of the salamander fauna, and 46% of the species of the genus *Eleutherodactylus* from this country.

In the introduction, the authors are explicit about the main

purpose of the book, which is to present the current status of our knowledge of the systematics and distribution of Honduran amphibian species. The volume succeeds in achieving this goal and will be a benchmark for all future herpetological studies in this country. The Material and Methods section outlines the plan of the book, and provides precise descriptions of the methodology used in each section, including the abbreviations and definitions of the morphological measurements used in the identification keys and species accounts.

The authors devote an entire chapter to describing the landscapes and environment in Honduras, thereby introducing the reader to the country. This chapter includes a general description of physiography, climate, and forest formations based on the authors' own work and observations. This section also includes habitat photos and maps illustrating the most prominent physiographic regions and forest formations. Following this introduction is a short chapter on the history of the study of amphibians in Honduras, complete with a chronological reference database for all published studies. This chapter also includes the three main published lists of Honduran amphibians with current names for all taxa.

The section on species diversity begins with clear and user-friendly identification keys to all orders, genera, and species, including those that have not been recorded from Honduras but are expected to occur in the country. When related species are very similar morphologically (salamanders for example) the authors have done a detailed morphometric analysis and use ratios of character combinations to aid in the identification of cryptic taxa. The authors also developed an extremely useful identification key to anuran tadpoles. The keys are accompanied by excellent illustrations, most of them previously published, but beautifully reproduced. Because the keys and illustrations are of excellent quality and because they are also presented in Spanish as well as English, this section of the book will be especially valuable to a wide audience, including Latin American students and researchers.

The bulk of the book contains the systematic accounts (410 pages) for each of 116 amphibian species. The authors provide a short introduction to each order, followed by a brief generic diagnosis that includes the reference to the original description, range, content, and etymology. Species accounts contain the reference to the original description and a chronological synonymy. Geographic and elevational ranges are described for each species. For the non-endemic Honduran taxa, their range in other countries is included as well. The authors point out the main diagnostic morphological characters. A very useful feature is that in some instances diagnosis is accompanied by a table of comparative measurements and proportions of selected characters for the species that is being described and other species with which it might be confused. The description of adult characters lists the material examined and provides a detailed description of each species, including color in life and in alcohol. Tadpole descriptions include a list of the material examined, characteristics of tadpole developmental stages, and a precise description including color in formalin. All accounts include also a list of published illustrations, and remarks, which are mostly comments on the latest taxonomic changes or phylogenetic relationships. For each species a section on ecological distribution and natural history contains basic ecological information mostly based on the authors' own observations. Maps are presented for most species, and excellent color photographs in life are provided for 110 of the 116 species. The quality of the identification keys and species accounts show the extent to which the authors are acquainted with every species from their own field experience, and this greatly enhances the utility of this volume. Following the species accounts, the authors provide a series of names of doubtful or probable occurrence in Honduras, with a short history of the species and the places where it might be found.

The chapter on reproductive modes and guild structure provides data for each species in tabular format. The authors recognize nine reproductive modes for anurans (all Honduran salamanders are direct developers, and the two species of caecilians are viviparous without an aquatic larval stage), eleven adult guilds, and thirteen tadpole guilds. The table for adult guild structures is a modified version of the classification of Heyer et al. (1990), and the table for tadpole guilds is a modified version of McDiarmid and Altig's (1999) classification. The inclusion of population biology and ecological data for these taxa is another example of the breadth of this book.

The authors include a chapter focusing on analyses of amphibian distributional patterns within ecological formations and by elevation, within physiographic regions, and within ecophysiographic areas. The results are presented in three tables that list all amphibians in Honduras and their status in each of the factors analyzed. The authors recognize eight ecological formations (excluding the montane rainforest), and assign each species to one of three categories: widespread, restricted, or peripheral. The results indicate that the three formations with the highest number of species are mesic forests. Honduras is subdivided into ten physiographic regions, and the analysis indicates that the highest number of species (46.3%) is found in the northern cordillera, which is the largest and most topographically and vegetationally complex region. In an ecophysiographic analysis, an update from the one presented by Wilson et al. (2001), the authors now recognize 38 areas. The results from this analysis are also presented in a table and on a map with the distribution of all 38 ecophysiographic areas. Finally, the authors allocate each species to one of the ten broad patterns of previously defined geographical distribution; this analysis indicates that 56.9% of species are either endemic to Honduras or restricted to Nuclear Middle America.

The last section of the book addresses environmental impact and the future of the Honduran amphibian fauna. A natural result of working in the field in Honduras for over 30 years is that McCranie and Wilson have personally witnessed the loss of amphibian diversity and have experienced first hand the accelerated habitat destruction as a result of the increase in human population. The authors effectively convey their frustration and anger at the environmental, social, and political situation in Honduras and do not hesitate in predicting a grim future for amphibian fauna if the current trends are not reversed. Honduras is one of the poorest countries in the Western Hemisphere and it is also one of the most rapidly growing countries in Central America. Not surprisingly, habitat alteration and destruction are identified as the major threat to the integrity of the herpetofauna of Honduras, but pollution and pest and predator control also play an important role. The authors suggest that the problem is so severe that we will all be witnesses to the depletion of the Honduras fauna and that diversity will be reduced to a few tolerant species. Other causes of amphibian

decline worldwide such as pathogen infections have also been detected in Honduras and climatic changes are also likely taking place. To evaluate the environmental vulnerability of each species, the authors consider three categories: geographic range (widespread to highly restricted), ecological distribution (according to the number of ecological formations where the species occurs), and specialization in reproductive modes (from general to highly specialized). The authors rate every species according to those three axes to create a composite environmental vulnerability score. Their results suggest that ca. 30% of the species have a poor chance of survival, 49% have a moderate chance, and almost 21% have a good chance of survival. The taxa with poor chances of survival are primarily Honduran endemics. McCranie and Wilson take this analysis one step further and evaluate the effectiveness of the existing system of Honduran biotic reserves. They conclude that 17% of the amphibian fauna are not protected by the existing system of biotic reserves. Furthermore, many of the existing reserves are not treated as such, and land clearing, lumbering, and ranching are widespread within the reserves. Despite the seemingly hopeless situation, the authors discuss a proposed system of biotic reserves that would protect most of the Honduran amphibian species (Wilson et al. 2001), thus clearly setting a framework for conservation action in this country. The final section of the book contains an abstract in Spanish, a glossary, and a useful gazetteer of all known Honduran collecting localities.

This book will be a necessary addition to the library of all herpetologists interested in Neotropical amphibians. It will also be a valuable tool to those with conservation management responsibilities in Honduras. Although it might be true, as some have claimed, that certain environmental problems in Latin America (such as those caused by overpopulation) are insoluble, and that conservation plans proposed by biologists are destined to fail, I believe that education will make a difference in the course of environmental actions in the next generations. McCranie and Wilson have done the only thing that can truly have an impact on the way Hondureños see their country and natural resources, especially young students who have access to this wonderful book (let's not forget the affordable price) and, who one day might be in the right place at the right time to make a difference for conservation of their fauna.

In 1970, William E. Duellman published a two-volume work on the hylid frogs of Middle America that became an instant classic and, eventually, a treasured item on book dealers' lists. As with any such book, however, Duellman's incomparable work grew increasingly out of date. As the twentieth century drew to a close, it became time for an update. The opportunity came in the form of a suggestion to Duellman from Kraig Adler to reprint the 1970 edition of the Middle American hylid book. Duellman bit at the hook proffered by Kraig, with the caveat, however, that Duellman would update the 1970 work.

Duellman's book consists of two fundamental parts. The first part is a reprint of the 1970 work, most of which comprises volume one. The second part is the supplement (including the new plates), which takes up most of volume two. Volume two also contains the appendices, literature cited section, and plates from the original work.

Inasmuch as the 1970 work is unchanged, there is no need to review this portion of the present work. The text of the supplement is 409 pages long. The new plates comprise twelve color paintings and eight black-and-white illustrations.

The introduction to the supplement provides the rationale for the update. The principal impetus was the increase (42.6%) of recognized taxa from 115 to 164 since 1970. Of the 49 species added, 39 were described as new from type localities in Mexico (19 species), Guatemala (8 species), Honduras (10 species), Costa Rica (1 species), and Panama (1 species). The remaining ten species are recognized as a result of taxonomic changes accruing since 1970. It is worthy to note that all of the 49 taxa are from highland habitats, indicating that prior to 1970, these areas have not been sufficiently well studied. It is interesting to consider that the 39 new taxa were described by a relatively few herpetologists, including, most notably, Jonathan A. Campbell, William E. Duellman, Larry David Wilson, James R. McCranie, and Joseph R. Mendelson.

The second section summarizes Middle American geohistory. Given the tremendous impact research into plate tectonics during the past three decades has had on our understanding of the geological changes that have occurred in Middle America, any attempt to understand the evolutionary history of hylid frogs has to be founded on these geological advances. Duellman's discussion is based in large part on a similar one in Campbell's (1999) influential paper. This section culminates in a discussion of the modern Middle American landscape, in which 23 ecogeographic regions are presented.

While acknowledging that the higher-level classification of the neobatrachian frogs is unresolved, in the section on the evolution of the hylid frogs, Duellman uses a suite of 24 characters to create a trio of equally parsimonious trees that support recognition of a clade of three neobatrachian families, Allophrynidae, Centrolenidae, and Hylidae (with the last reducing the Pseudidae to a subfamily). Which of the families Allophrynidae or Centrolenidae comprises the sister taxon of the Hylidae is unresolved, due to the lack of pertinent data on three characters for the Allophrynidae. Nonetheless, with the inclusion of the pseudid frogs, the Hylidae appears to be a monophyletic taxon. Duellman recognizes five subfamilies (Pelodryadinae, Phyllomedusinae, Hemiphractinae, Pseudinae, and Hylinae) within the Hylidae for which taxa he provides a classification. The Phyllomedusinae (genera *Agalychnis* and *Phyllomedusa*), Hemiphractinae (genera *Gastrotheca* and *Hemiphractus*), and Hylinae (genera *Anotheca, Duellmanohyla, Hyla, Phrynohyas, Plectrohyla, Ptychohyla, Scinax,* and *Smilisca*) have members occurring in Middle America. Duellman indicates that *Hyla*, with 318 species, is both paraphyletic and polyphyletic; thus, it stands as a major impediment to clarifying our understanding of the evolution of hyline anurans. Nevertheless, Duellman devotes the next 11 or so pages to a discussion of the evolutionary history of hylid frogs, with most emphasis placed on those of Mesoamerica. This discussion is based on his own work (Duellman, 1979) and that of Jay Savage (1966, 1983). The conclusion of greatest interest and import to Duellman's discussion is that evidence was presented in the earlier works for recognition of an autochthonous Middle American herpetofauna arising from a series of vicariance and dispersal events. Savage's views have recently been updated in his monumental book on the herpetofauna of Costa Rica (Savage, 2002). Duellman divides his story into six chapters, as follows: (1) the movement of hyline and phyllomedusine stocks into Middle America from South America; (2) differentiation of North American and Middle American basal lineages; (3) dispersal of several montane lineages in the Mexican, Nuclear Central American, and Isthmian highlands, most containing stream-breeders; (4) vicariance of the generalized North American lineages caused by increasing aridity in southwestern North America; (5) differentiation of the Middle American basal lineage into lower Central American and Mexican-Nuclear Central American lineages early in the Cenozoic; (6) past the closure of the Panamanian Portal in the mid-Pliocene, dispersal of hylid frogs to a considerable extent northward and a more limited extent southward, related to the comparatively larger number of hylid species in northwestern South America than in lower Central America. In his discussion of the events of the fifth chapter, Duellman states (p. 781) that, "As the Isthmian Highlands rose in the Miocene and Pliocene, a vicariance of the Lower Central American lowland lineage gave rise to an Isthmian highland lineage in the uplifted region of lower Central America. This lineage differentiated into *Ptychohyla* and the *Hyla pictipes* and *H. pseudopuma* groups." The idea of a Lower Central American origin of the Mexican and Central American highland genus *Ptychohyla* seems curious, until one realizes that a single species (*Hyla legleri* auctorum) placed in this putative genus by Campbell and Smith (1992) and Duellman (in the book under review) occurs in Costa Rica and extreme western Panama. Although Savage (2002) recognizes the Campbell and Smith (1992) genus *Duellmanohyla*, he stated, "The transfer of *Hyla legleri* to *Ptychohyla* seems to be on less secure ground, and here it is retained in *Hyla*." The unlikelihood of Duellman's postulate of a lower Central American origin for *Ptychohyla* is further strengthened by his statement (on p. 783) that, "Three lineages of stream-breeding hylines (*Duellmanohyla, Ptychohyla,* and *Plectrohyla*) had independent histories in Nuclear Central America," and yet further by the statement, "An early southward dispersal of the basal lineage of *Ptychohyla* resulted in the isolation of a population (*P. legleri*) in the Isthmian Highlands and *P. salvadorensis* in Nuclear Central America…." Another distinction between the book under review and Savage's (2002) work is in the composition of the Hyla *pictipes* group of Lower Central America. Duellman places 11 species in this group, including *Hyla insolita* of Honduras and *Hyla throrectes* found in the Mexican Highlands. His *pictipes* group represents a combination of the former *Hyla lancasteri, pictipes, rivularis*, and *zeteki* groups. Savage (2002), on the other hand, recognizes three of the four groups Duellman placed in his *pictipes* group, viz., *lancasteri, pictipes* (plus *rivularis* group), and *zeteki* groups. Even at the group level within the troublesome *Hyla*, there are major differences in systematic opinion from one worker to the next, which means that explanations of hyline evolution are similarly rickety.

The fourth section deals with distribution and diversity of Mesoamerican hylids. Duellman discusses the patterns of distribution within 23 ecogeographic regions, as well as elevational distribution, and hylid frog communities. Duellman notes an interesting correlation between geographic distributional patterns and reproductive mode, with 90 of 124 species of highland frogs being stream-breeders and 31 of 35 species of lowland frogs being pond breeders. Expectedly, ponds are more common in lowland than in highland areas. The figure just cited for species of lowland frogs (35) does not agree with the number given in the first sentence of the following topic, which is 52 (and that number is also incorrect, according to the data in Appendix 4, in which 53 species are indicated to occur in the lowlands). Of these 53 species, most belong to the Middle American element, a somewhat smaller number to the South American element, and a small number to the North American element. Duellman concludes that in the lowlands there is a general increase in species richness from higher to lower latitudes. Of the 124 species in the highlands, the large majority is in the Middle American element, with comparatively very small numbers in both the North American and South American elements. Of the 111 Middle American element species, all but two are endemic to Middle America. In the Mexican highlands and Mexican Plateau, as evidenced by one of the diagrammatic representations found in this topic area, the largest number of species and the greatest degree of endemism are found in the Sierra

Madre Oriental, followed by the figures for the Sierra Madre del Sur. Within Middle America, the greatest species richness and degree of endemism are found in the Nuclear Central American Highlands, followed by the Isthmian Highlands. These two areas are highly distinct from one another (they share only a single species) and from the areas both to the north and to the south, further emphasizing Middle America as a center of hylid evolution and endemism. With respect to elevational distribution, Duellman concludes (p. 797) "...the number of species increases from the lowlands to elevations between 500 and 2000 meters and then declines rapidly at higher elevations...." He further notes that, "Elevational distribution seems to be most closely correlated with suitable sites for tadpole development," with most ponds, and therefore, most pond-breeding species being found in the lowlands, and small, clear-water streams, and, consequently, stream-breeding species occurring in the highlands. The final portion of this section deals with hylid frog communities, with Duellman pointing out that local anuran communities are well documented at only a few localities in Mesoamerica. Duellman assembled data on hylid communities at 36 sites in Middle America concerning habitat type and reproductive mode. Species richness is expectedly lower in the drier sites, i.e., 4–7 species in dry forest and 4 and 6 in two coniferous forest sites, and higher in more humid sites, i.e., 5–12 in tropical rainforest and 5–11 in cloud forest.

The fifth section is concerned with biogeographic comparisons with other taxonomic groups, including amphibians in general, the genus *Eleutherodactylus*, and bolitoglossine salamanders. After noting (p. 803), "Generalized comparisons with other taxonomic groups of Middle American biota for the most part are comparable with the proposed evolutionary history of Middle American hylid frogs," Duellman discusses biogeographic patterns among amphibians and confirms that Middle America has been an important center of evolution and radiation for these creatures and that various amphibian groups other than hylid frogs have been affected in similar ways by the major geophysical events discussed above. The huge genus *Eleutherodactylus*, the most speciose of vertebrate genera, has been divided into five subgenera, three of which have representatives in Middle America. Duellman notes that the scenario accounting for the presence of these three subgenera is hampered by the counterintuitive sister-group relationship proposed by Haas and Hedges (1991) and Hedges (1996) between the Mesoamerican subgenus *Syrrhophus* and the West Indian subgenus *Euhyas*. The other elements of the scenario involve a Late Cretaceous-Eocene dispersal from South America of the lineage that gave rise to the members of the subgenus *Craugastor*, followed by a post mid-Pliocene dispersal from South America of lineages of the subgenus *Eleutherodactylus*. Duellman notes that diversity of *Eleutherodactylus* is greatest in the highlands of Middle America; within this region, the greatest species richness and degree of endemism occur in the Nuclear Central American Highlands and the Isthmian Highlands. The Middle American bolitoglossine salamanders represent a clade derived from northern stocks, unlike the history of *Eleutherodactylus*. All but two of the bolitoglossine genera (*Bolitoglossa* and *Oedipina*) are endemic to Middle America, with the two exceptions occurring to some extent in South America (*Bolitoglossa* contains 20 endemic South America species). Duellman indicates that the three major Middle American highland areas are the centers of radiation for this group of salamanders. The greatest numbers of species and degree of endemism occur in the Sierra Madre Oriental, Sierra Madre del Sur, Nuclear Central American Highlands, and the Isthmian Highlands. These four areas are remarkably distinct from one another in species composition, sharing no more than one species between pairs of areas.

The sixth section on conservation is a small one, covering two major topics, protected areas and declining amphibian populations. Anyone who has worked in Middle America for a lengthy span of time has witnessed a hugely disconcerting loss of habitat, primarily due to deforestation to make way for croplands and pasturelands for the support of uncontrolled human population growth. Duellman notes the seemingly large number of protected areas in Mexico (117) and Central America (about 140). Although such a large number of protected areas looks good on paper, these areas are oftentimes subjected to varying degrees of human disturbance, in turn due to pressure exerted by burgeoning human populations. Furthermore, the biota found in these areas is often poorly known. These concerns are receiving increasing attention by herpetologists and conservationists (references in Duellman's book and Wilson et al. 2001). Duellman also briefly discusses the problem of declining amphibian populations, formal notice of which took place at the First World Congress of Herpetology in 1989. Duellman reviews the various postulated causes of this decline, paying greatest attention to the influence of chytrid fungal infections, which degrade keratinous tissue. He postulates that these infections could eventually affect about 85 percent of the Middle American hylid species and possibly eliminate about 65 percent of the Middle American hylid faunal element, "... including essentially all of the montane radiations ..." (p. 817). Such disappearances should be expected to reverberate through highland food webs, being especially devastating to batrachophagous predators.

Future research is discussed in the seventh section. Duellman indicates that not all Middle American hylid species have been discovered. For example, work in southern Mexico is adding to our knowledge of the hylid fauna there (e.g., Canseco-Márquez et al. 2002). Some species may be composites and require future segregation. Tadpoles remain to be described for several species. Some morphological characters have been poorly studied and molecular data are nearly completely unavailable for Middle American hylids. Its unavailability in hylid frogs strikes an especially poignant note in light of the population declines documented in the previous sections, inasmuch as molecular data are most easily gathered from living examples. We may simply be too late for some of this kind of work, as Duellman indicates. In addition, other aspects of the biology of hylid frogs are noted to be poorly understood, especially ecophysiology and ethology. Duellman expresses his hope that his dreams for the use of available biological stations to conduct future work on the biology of hylid frogs will not be dashed by continued anthropogenic destruction and declining amphibian populations.

The eighth section contains the tables and dichotomous keys intended for identification of Middle American hylids. A four-page table provides an update of the diagnostic features of Middle American hylid tadpoles described since 1970. This table complements a similar one in the 1970 work. The dichotomous keys to adults are new and complete, organized into sections dealing with species from northwest of the Isthmus of Tehuantepec, from

the Isthmus of Tehuantepec through Nicaragua, and from Costa Rica and Panama.

As expected, the largest portion of the supplement is the ninth section, which presents the generic and species accounts. Some species groups are also considered. Treatments of the hylid genera range from no new information (*Hyla*) to extensive summarizations (*Agalychnis, Duellmanohyla, Plectrohyla, Ptychohyla*, and *Smilisca*), including cladistic analyses generating cladograms. None of the cladograms presented for these five genera are fully resolved, pointing to the need for analyses using additional characters suites not traditionally considered. Duellman also discusses several species groups within *Hyla*, including the *albomarginata, bistincta, boans, bogotensis, bromeliacia, eximia, godmani, leucophyllata, microcephala, miliaria, miotympanum, mixomaculata, parviceps, pictipes, pseudopuma, sumichrasti*, and *taeniopus* groups. Cladograms are presented for several of these groups, with only the ones for the *bistincta* and *miotympanum* groups being full resolved. Of considerable interest is the relationship between the *Hyla bistincta* group and the genus *Plectrohyla*. Duellman postulates that these two groups comprise a clade defined by four synapomorphies (his Fig. 432). These two groups are allopatric, distributed to the west and east of the Isthmus of Tehuantepec, respectively. His new analysis supports the contention of Duellman and Campbell (1992) that the *Hyla bistincta* group is the closest relative of *Plectrohyla*, which renders the genus *Hyla* paraphyletic. In the case of species-level taxa, accounts are most complete, of course, for species described since 1970. The first such full-fledged account is that for *Hyla graceae*. It is exemplary of other such accounts and contains sections on synonymy, diagnosis, description of adult, description of tadpole, mating call, natural history, remarks, etymology, and distribution, the same categories used in species accounts in Duellman's 1970 work. Several updated distribution maps pepper this section, as well as illustrations of tadpoles and their mouthparts, ventral hand (or thumb) and foot surfaces, and audiospectrograms. A number of tables are distributed among the accounts, including the character matrices that support the cladograms. In general, these accounts represent a masterful synthesis of a huge amount of information that has accumulated in the last three decades.

The Literature Cited section for the supplement contains 450 references, with an up-to-the-minute coverage indicated by several inclusions with 2001 publication dates. This section, along with the citations to this literature in the text, will allow any interested person to follow the history of the changes that have occurred in our knowledge of Middle American hylids from 1970 to 2001.

Four appendices are attached to the end of the text of the book. Appendix 3 is a compilation of data on distribution of hylid frogs, *Eleutherodactylus*, and bolitoglossine salamanders among the 23 ecogeographic regions of Middle America and occupies 15 pages. Appendix 4 is a listing of data on elevational distribution, habitat type, oviposition site, and tadpole site for all Middle American hylids. Appendix 5 is an extremely valuable 27-page listing of locality records and the museum of location of the voucher specimens, which supplements Appendix 1 from the 1970 work. This information will allow any interested workers to locate specimens for their own research. Appendix 6 provides locality data and specimen numbers for the illustrations on the new plates.

The index covers the text of both the original 1970 work and the supplement. It also references the plates in both treatments, all of which follow this section.

The plates comprise the last section of this two-volume work. The 72 plates from the original work are placed here and are followed by twelve color plates and eight black-and-white plates. The new plates are also the work of the superb herpetological artist David M. Dennis. The twelve color plates contain 50 paintings of adults of 42 species and the black-and-white plates comprise 26 paintings of adults of five species, hands and feet of one species, tadpoles of twelve species, and tadpole mouthparts of seven species. These illustrations will be a major attractant to potential purchasers of this book.

The major question I believe that will occur to those who have depended in the past on the 1970 work is whether it might have been preferable for Duellman to have crafted a full-scale revision of his classic work, instead of producing an update and publishing it as a supplement to the original work. This might especially occur to those people who have a copy of the original work for which they paid $25 dollars for a new copy. Sixty-five percent of the pages and 78 percent of the plates in the book under review were in the original. In essence, people who have both works paid $100 for 35 percent of the pages and 22 percent of the plates in the new book. Incidentally, this is not the first time Duellman has produced an update of this type, although in that work (Duellman 1993) he was updating the work of another person (Frost 1985) and Duellman's supplement was not attached to a reprinting of Frost's work. I think the answer to this question is that it definitely will hurt the pocketbooks of those who have the original work, but given the design of the new book, there is no alternative to its purchase, if the purchaser is interested in the hylid frogs of Middle America.

The book will have more obvious appeal to those who do not have a copy of the original or did not care to shell out $300 for a used copy from a book dealer. From the perspective of these people, the new book is a bargain at $125, especially as it is updated to the year 2001. Younger people similarly interested in Middle American hylids also will have to have this book. In sum total, Kraig Adler and William Duellman have cleverly crafted a book that will have to be on the wish list of any herpetologist, young or old, working in Middle America, not to mention the Caribbean and South America.

The reading I did of this book for this review illustrates that the supplement is practically free of errors. I noted only one minor concern. On page 817, Duellman writes, "Many conservationists decry collecting and uniformed bureaucrats often make obtaining collecting permits a costly and time-consuming process, while habitat destruction continues unabated." He meant to write "uninformed bureaucrats," although I am not entirely sure the phrase doesn't work the way it was printed.

The 1970 work was branded "... the Hope diamond of technical herpetological literature" in the review by Hobart M. Smith (1971: 379). It is clear that Duellman, with this supplement, has excavated another diamond, perhaps not of the size and brilliance of the Hope diamond, but still a jewel of distinction. This work is characterized by the high quality Bill Duellman brings to his herpetological work, with the result that the supplement is a rich storehouse of valuable insights into the nature of the Middle American hylid fauna that will be giving up its stores for decades to come. Bill Duellman's

career to date has been a fascinating one to follow, from the days when he counted snake scales to the present day when he is a reigning world authority on the systematics of hylid frogs and amphibians in general.

The *New Encyclopedia* is a revision of the popular 1986 original published in the Facts on File Animal Series in North America. The new edition is 100 pages longer than the original and, in line with technology now available, is more profusely and elegantly illustrated with spectacular color photographs. Textual material was prepared by 37 pre-eminent herpetologists, primarily from the UK and USA, 19 of whom contributed to the first edition. The authorship of each section is indicated by the contributor's initials at the end of each covered topic. The first edition was translated into 18 languages and new editions in these languages will be issued over the next several years.

Strictly speaking this is not an encyclopedia as the organization is not by an alphabetical treatment of topics. Rather, the book, as well as its predecessor, is organized along evolutionary lines with each group of amphibians and reptiles covered in order from presumed primitive to advanced taxa.

Major articles introduce amphibians (pp. 10–36) and reptiles (pp. 98–117), present sections on classification and taxonomy, evolutionary history, and a spectrum of information on physiology, ecology, and biology. These articles are followed by main entries on the major groups of living amphibians (the usual three) and reptiles (6), including amphisbaenians as a separate group. These are each introduced by a boxed "Factfile" summarizing composition, distribution, habitats, size, coloration, longevity, and conservation status. The Factfile also contains scale drawings of size ranges found in the group compared to a 1.8 m human being.

The main text gives general coverage on the form and biology of its members with emphasis on unusual or unique features. This is followed by a section on each recognized family within multi-family groups (except in the case of caecilians, worm-lizards and

crocodilians) dealing with important taxa and interesting facets of their biology. At the conclusion of the entries for salamanders and newts, frogs and toads, turtles and tortoises, lizards, and snakes summaries on the families within each group are presented in tabular form. Each table includes brief sections on composition (numbers of genera and species), distribution, example taxa, size, color, and conservation status. Additional sections on breeding (i.e., reproduction) for amphibian families, diet and eggs for turtle families, and scales for lizard and snake families, are also featured. A small colored distribution map is provided for each family. While a bit of this material is redundant to what is included in the main text on each major group, it makes for ready reference and comparison among families.

The new edition has expanded its coverage of interesting aspects of the life of amphibians and reptiles that have broader implications to biology as a whole. This is done in a series of double-page Special Features scattered throughout the text. Revised sections from the original, now Special Features, are: A Key Amphibian Event; Kaleidoscopic Adaptation; Conscientious Parents; Courtship and Mating in Salamanders and Newts; Repellent Defenders; Leaps and Bounds; Decoding the Frog Chorus; The Age of Reptiles; Temperature Control in Reptiles; Venomous Snakes. New Special Features are: Classification and Taxonomy; Amphibian Population Decline; Amphibian Conservation; Swimming, Eating and Growing Machines; From Tadpole to Frogs; Reptiles at Risk; Play in Reptiles; Pre-ejaculators, Sneakers, and She-males; Temperature and Sex; The Asian Turtle Crisis; Natural Desert Dwellers; The Threat from Snakebites; Pollution and Hormone Mimics; and Unisexuality: the Redundant Male. Two "Photo Stories" on Leatherbacks: Birth on the Beach and Harvesting Snake Venom, are other new features.

The book is enhanced on nearly every page by color photographs of amphibians and reptiles in nature. Many are from the first edition but a substantial number are brand-new. The impact of these is extremely effective because of the large format (29 x 23 cm). Fifteen splendid artwork panels, mostly by David Dennis, grace this book. Many are from the first edition but improved by advances in printing technology and paper quality over the original reproductions. Some individual portraits of species have been dropped and several additional taxa have been added, especially to enhance the charm of the preliminary material on pp. 4–7. The illustrations of fossil forms is reduced and mostly replaced by new ones. Frankly, I liked the ones from the first edition better. Numerous line drawings provide additional information.

This is truly a wonderful introduction to the world of amphibians and reptiles and lives up to its dust jacket superlatives of spectacular photography, authoritative, and up-to-date. It is a fine resource for anyone interested in herpetology in the broadest sense. It will also be useful as a supplement to courses in herpetology given at the upper division or graduate level but lacks the necessary technical consideration of systematic characteristics to be used as a stand-alone text.

I come from the generation of herpetologists who, fascinated by amphibians and reptiles while growing up, cut their herpetological teeth on books by Raymond L. Ditmars (I bought my first one when I was 12) and Mary C. Dickerson's *The Frog Book*. No one then could imagine the quality and quantity of resources available to an aspiring member of our discipline today. The Halliday and Adler work, the comparable encyclopedia of Cogger and Zweifel (1998) and the textbooks by Pough et al. (2001) and Zug et al. (2001), all are now available to stimulate and educate the beginning and more advanced student in the quest to understand our favorite creatures. I strongly recommend that the *New Encyclopedia* join the other three on the shelves or desks of anyone seriously interested in amphibians and reptiles. It is a fine reference source and its visual images are aesthetic delights that will be returned to many times.

I was pleased to hear that Cornell University Press intended to reprint Wright's *Life-Histories of the Frogs of the Okefinokee Swamp*. I am fortunate to have an original copy of the book and it is truly one of the most useful references on my shelf. As such, it is appropriate that this still-valuable reference be made readily available to researchers and students alike. The Okefenokee Swamp is one of the most significant wetlands in the world and Wright's book is unparalleled in terms of its detailed information on the life-histories of frogs of the region. The hardcover edition is affordable and with just a few minor alterations in layout the book is essentially identical to the original. The new edition is enhanced by a Foreword and Afterword written by J. Whitfield Gibbons, outlining the justification for reprinting the book after nearly 80 years and summarizing the current state of our knowledge of the swamp and its amphibians.

In the Foreword, Gibbons outlines the history of the Cornell expeditions, associated publications and the subsequent scientific careers of those involved in the early expeditions, including Sherman Bishop, Alvin Cahn, and Francis Harper. He also provides an overview of the geologic and land use history of the swamp, pointing out that the swamp is not pristine, having been logged and subject to drainage alterations prior to President Franklin D. Roosevelt's designation of the swamp as a National Wildlife Refuge in 1937. Even after this designation, in the 1960s an impoundment structure (the Suwannee River Sill) was built to retain water within the swamp in an attempt to prevent the spread of wild fires to surrounding private timberlands. In 1974, more than 350,000 ac of the Refuge were designated as a National Wilderness Area, which limits invasive activities such as the use of high powered motor craft in the Refuge.

The body of the book includes the original preface, introduction, acknowledgments, a review of previous and subsequent expeditions to the region, a description of the plant communities of the swamp, followed by a general discussion of the Okefinokee Salientia. The "general" discussion includes everything from the geographic range and habits of 22 species of anurans, to the specifics of larval development, a breadth that is rarely attempted in recent works. This section includes details on morphology of various species at different developmental stages, dichotomous keys to anuran eggs and larvae, as well as lists of subjects for which only incomplete information was available at the time. The accounts of species follow; these include common names, range (including local Okefenokee records), and extensive life history information. For each species, Wright provides a chronologic review of the literature on topics such as egg laying and vocalizations, followed by meticulous firsthand descriptions of these behaviors by Cornell expedition members. I find that the descriptions and photographs of eggs and larvae are particularly useful, since this level of detail is not provided in regional field guides. The quality of the illustrations and black-and-white photographs is quite good. The plates include lateral aspects of adults, examples of normal and abnormal amplexus, egg masses, larvae in different developmental stages, and illustrations of tadpole mouthparts for 25 species.

The Afterword includes an update of the nomenclature of southeastern anurans, which is little changed from Wright's accounts. Gibbons also reviews the subsequent herpetological research in the swamp, pointing out that there has been only limited research since the Cornell Expeditions. He suggests that the swamp be used as a reference site to represent "normal" conditions for anuran populations in the southeast. Having worked in the Refuge recently (2000–2001) as a biologist for the U.S. Geological Survey (USGS), I fear that this assessment of the state of the swamp may be overly optimistic. Although there are a few small stands of large cypress in the swamp interior today, impenetrable shrub thickets of invasive species which thrive in disturbed conditions—titi (*Cyrilla racemiflora*), hurrahbush (*Lyonia lucida*), and fetterbush (*Leucothoe racemosa*)—cover nearly 30% of the swamp (Loftin 1998). We found that the primarily aquatic ranids such as the pig frog (aka southern bullfrog; *Rana grylio*), bronze frog (*Rana clamitans*), and carpenter frog (*Rana virgatipes*) were still broadly distributed within the swamp (Smith 2001). However, the impact of the vegetation changes in the swamp on amphibian populations is entirely unknown. Furthermore, populations of pond-breeding amphibians such as the Florida gopher frog (*Rana capito*), striped newt (*Notophthalmus perstriatus*), and flatwoods salamander (*Ambystoma cingulatum*) may not be secure within the Refuge. Only 5% of the Refuge is upland forest (Loftin 1998) and most of the land surrounding the Refuge is intensively managed for timber. Although the pinelands in the Refuge are managed with prescribed fire (for red-cockaded woodpeckers), few areas even begin to resemble those depicted in the 1921 photograph of Siren's Run on Billy's Island (Plate XXI, No. 1). Surveys by Jensen (1995) and the USGS (Smith 2001) failed to confirm the presence of flatwoods salamanders on the Refuge and only one striped newt breeding pond has been identified in recent years (Dodd and LaClaire 1995). The pond is transected by two service roads; a sad reminder that no part of the Refuge can be considered pristine.

Finally, I had to look long and hard to find errors in the reprinted version of the book and those that I did find were very minor typographical mistakes. For example, in Plate XXIV, image 2 the word "make" appears instead of "male" and on page 479, paragraph 2 of the afterword, it should read E.D., rather than A.D. Cope. The reproductions of the original black-and-white photographs were excellent and in some cases even better than the original. The only other notable differences between the original and reprinted version is that the photo of Leonhard Stejneger that accompanied the dedication was not included, and the photographic plates were grouped in the new version rather than spread throughout the volume. In short, I found the re-issued volume to be of excellent quality.

In addition to the very detailed species accounts, Wright included a list of life history subjects for which only incomplete data were available at the time. Many of these intriguing questions remain unanswered. For example, it can be argued that we still do not fully understand the relationship in range and habitat partitioning between *Rana grylio* and *R. catesbeiana*. And we still lack knowledge about the habits of young gopher frogs (*Rana capito*). The re-issue of this valuable book might well stimulate research interest in the amphibians of the swamp.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ukans.edu/~ssar/HRinfo.html#cont>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor or Managing Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR Treasurer (Dr. Theodora Pinou; contact information on inside front cover) or from the SSAR web page (http://www.ukans.edu/~ssar/HRadRates.html).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Donald Schmitt, SSAR Membership Office, P.O. Box 253, Marceline, Missouri 64658, USA. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below) regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 760	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com.

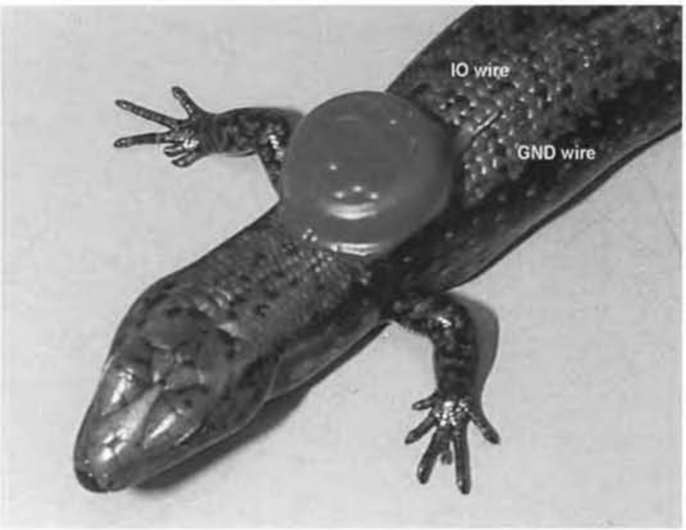

FIG. 4. A female *Eulamprus tympanum* fitted with a modified Thermochron iButton.

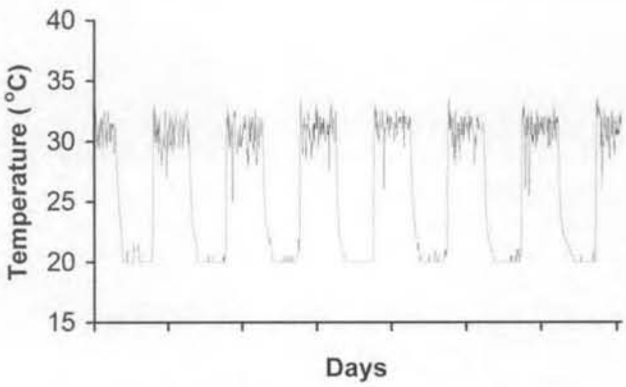

FIG. 5. Thermal profile of a captive female *Eulamprus tympanum* over one-week at a 5-minute sample rate.

clip can then be attached to the exposed IO wire on the unit. Another wire should be coiled around the outer contact of the reader with the opposite end attached to the exposed GND wire on the unit also with a small alligator clip (Fig. 3). After testing the soldered unit, it should be sealed to ensure it is watertight with Plastidip™ (Minnesota, USA) (www.PLASTIDIP.com) with the exposed ends of the IO and GND wires emerging from the Plastidip™ (Fig. 2).

We tested the modified unit on six gravid female *Eulamprus tympanum* over several weeks in laboratory enclosures. Lizards were housed individually in 620 x 400 mm enclosures with 20–30 mm depth of soil, flat rocks and leaf litter for shelter. Lizards were provided with heat from 100 W incandescent bulbs at one end of their enclosure to allow them to thermoregulate. Enclosures provided a thermal gradient of 20 to 40 ± 1°C during daylight hours and 20 ± 1° C during the night. The modified units where attached to the backs of lizards with Super Glue™ (cyanoacrylic glue) behind the head, between the shoulder blades (Fig. 4) and gave continuous measurements of temperature at 5-minute. intervals (Fig. 5). Measurements can be downloaded and units can be re-launched while the unit remains attached to the animal. The unit will detach from reptiles upon shedding or acetone can be applied to the site of attachment to remove the unit prior to shedding.

Acknowledgments.—I thank Patrick Evans from iButton support, Joerg Suckau and Basil Panayotakos from the School of Biological Sciences workshop for technical advice. Lizards were collected under scientific licence from the New South Wales National Parks and Wildlife Service (B2082) and research was approved by the University of Sydney Animal Care and Ethics Committee (L04/10-98/1/2855). The project was supported in part by an ARC Large Grant to M. B. Thompson and by an Ethel Mary Read Research Grant from the Zoological Society of New South Wales to K. A. Robert.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 34, Number 1 (March 2003).

CAUDATA

AMBYSTOMA TIGRINUM (Tiger Salamander). **PREDATION**. Although a wide variety of birds have been documented or implicated as predators of *Ambystoma tigrinum* (Lannoo and Phillips, *in press*. *In* M. J. Lannoo [ed.], Status and Conservation of U.S. Amphibians. Univ. California Press, Berkeley), most of the species target aquatic larval forms. On 19 June 2001 in Taylor County, Georgia, USA, I encountered a cache of numerous animals impaled on a barbed-wire fence by loggerhead shrikes (*Lanius ludovicianus*). Herpetofauna found among the cache included several adult *Hyla squirella* and *H. cinerea*, and one post-metamorphic *A. tigrinum*. Although amphibians have been reported in the diet of loggerhead shrikes (Yosef and Grubb 1993. Condor 95:127–131), I believe this is the first reported observation of loggerhead shrikes predating a salamander.

The barbed wire fence surrounded an agricultural field that contained an isolated wetland used for breeding by a variety of amphibians, including *A. tigrinum*. At the time of the observation, the field's vegetation was low, which may have helped the shrikes see small amphibians dispersing from the wetland.

Submitted by **JOHN B. JENSEN**, Georgia Department of Natural Resources, Nongame-Endangered Wildlife Program, 116 Rum Creek Drive, Forsyth, Georgia 31029, USA; e-mail: john_jensen@dnr.state.ga.us.

ANEIDES VAGRANS (Wandering Salamander). **REPRODUCTION.** *Aneides vagrans*, a sibling species with *A. ferreus*, is a terrestrial forest-dwelling plethodontid salamander found on Vancouver Island (and smaller adjacent islands), British Columbia, and in northwestern California (Jackman 1998. Can. J. Zool. 76:1570–1580). There are few published descriptions of the eggs, clutch sizes, or nest sites of either species. Herein I report five *A. vagrans* egg clusters from Vancouver Island with descriptions of nest cavities, adult attendance, and hatching size.

In 1988 I found three clusters of *A. vagrans* eggs 200 m southwest of Hwy 19, 0.5 km S of Rosewall Creek, north of McNaughton Creek (49°27' N, 124°46' W). The site had been selectively logged within the last 100 years, but contained at least a few very old trees (estimated at > 200 years). Egg clusters were suspended from the roof of small cavities under the bark of Douglas-fir (*Pseudotsuga menziesii*) logs 1.0–1.5 m in diameter in a mid-to-late state of decay with partly rotted interiors and bark that could be removed easily by hand. Eggs were attached individually by gelatinous strands to a single point on the roof of the cavity and the strands from all the eggs were twisted around each other so that the eggs hung in a grape-like cluster typical of *Aneides* (Miller 1944. Copeia 1944:224–230; Storm 1947. Herpetologica 4:60–62; Canterbury and Pauley 1994. J. Herpetol. 28:431–434; Stebbins and Cohen 1995. A Natural History of Amphibians, Princeton University Press). The sex of attending adults was determined by post-mortem examination of the gonads.

The first clutch was found on 23 June 1988, and consisted of nine eggs in a cavity 140 mm wide, 70 mm high, and 35 mm deep. The nearly spherical, smooth, cream-colored eggs each measured 5.6 mm across the horizontal diameter. An adult female *A. vagrans* (SVL: 69.6 mm; BM: 5.6 g) was in the cavity with the eggs. The eggs were brought back to the laboratory and embryos could be seen developing within them, but by 8 July 1988, the eggs were infected by fungi (as evidenced by hyphae), and presumed dead.

The second clutch was found on 29 June 1988 and consisted of 14 eggs, The eggs were similar in size (5.5 mm across the horizontal diameter), shape and appearance to the first clutch. Also, the cavity was similar in size and shape to the cavity described above. Two adult salamanders of undetermined sex (SVL: 63.0 mm, 55.7 mm; BM: 4.9 g, 3.5 g) were found under bark within 20 cm of the eggs on opposite sides of the nesting cavity.

The third clutch was found on 23Aug 1988, and consisted of 3 eggs. An adult female *A. vagrans* (SVL: 62.3 mm; BM: 3.0 g) was in the cavity (width, 120 mm; height, 31 mm; depth, 24 mm) with the eggs. The eggs measured 6.2 mm across the horizontal diameter and 7.4 mm across the vertical diameter. The salamander and eggs were brought back to the laboratory, but after two days, one of the eggs had disappeared, apparently having been eaten by the salamander. I removed the adult and kept the two remaining eggs moist, but not wet. By the end of September, the eggs were dark brown and wrinkled on the surface, but there was no evidence of fungal hyphae. Between 2 and 10 October 1988 both eggs hatched. I fed the hatchlings (SVL: 15.7 mm, 15.3 mm; total length: 24.3 mm, 23.4 mm; BM: 0.093 g, 0.089 g) wingless *Drosophila* for several months, but the salamanders were dead, for no obvious reason, by 16 Feb 1989.

On 7 Sept. 1998, two clusters were found by R. Hyatt on Thetis Island, British Columbia (49°00'N, 123°40'W) and brought to me the following day. These clusters were in a 0.7 m diameter Douglas-fir log that had been felled about 18 months earlier and was mostly solid. The clusters were 12 cm apart within a hollow section of the log, 10–40 cm from one end of the log, and ca. 25 cm below the surface. Hatchlings were emerging from the egg capsules. One cluster had 15 unhatched eggs and 13 empty egg capsules, and the other cluster had 1 unhatched egg and 11 empty egg capsules. Thus, the clutch sizes were 28 and 12. The mean body mass of 23 hatchlings, measured ten days after hatching was 0.09823 g, SD = 0.0096, range 0.0763–0.1135 g. SVL and total length were measured with vernier calipers, but because the animals were difficult to restrain, only approximate measurements of the total length are reported here. Mean SVL was 14.3 mm, SD = 0.27, range 14.5–13.0 mm, and total length was about 25 mm. Hatchling coloration and total length were similar to that reported by Storm (1947, *op. cit.*) for seven *A. ferreus* hatchlings in Oregon.

Some of this work was done in partial fulfillment for the requirements of an M.Sc. degree at the University of Victoria, Victoria, British Columbia, Canada. The egg clusters from Thetis Island were found by Richard Hyatt, collected by Jeannine Caldbeck, and the number of eggs in each clutch was counted by Kristiina Ovaska and me. Kristiina Ovaska and Patrick Gregory offered helpful comments on an earlier manuscript.

NOTOPHTHALMUS VIRIDESCENS LOUISIANENSIS (Central Newt). **BRANCHIATE ADULT.** The life cycle of *Notophthalmus viridescens* has been described previously by many authors, but only a few branchiate adults (those possessing retained gills) have been reported. We collected 17 *N. viridescens louisianensis* from a small partly wooded, man-made pond on 26 Jan 2002. This pond was located ca. 0.4 km E of Taylor Road within T20N R3W Sec 4, Randolph County, Arkansas. Upon examination we discovered one branchiate adult that appeared in every other respect to be an adult aquatic form. The individual possessed external gills, gill slits, and free opercular folds. This observation appears to be the first recorded instance of this morphology from Arkansas. The locality where this individual was collected has been subjected to a multi-year drought that undoubtedly spanned the lives of the branchiate individual, its parents, and possibly the grandparents. The pond is permanent and fishless. These combined attributes may have induced the expression of branchiate phenotypes within this Ozark population, since this

morphotype had not been discovered during previous visits to the site. It will be interesting to monitor the occurrence of branchiate individuals in this population to investigate the ecological triggers causing expression of this trait.

Box 847, State University, Arkansas 72467, USA, and **STANLEY E. TRAUTH** (e-mail: strauth@astate.edu), Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA.

PLETHODON IDAHOENSIS (Coeur d'Alene Salamander). **COLORATION.** We are reporting an unusual melanistic adult (4.1 cm SVL) found 24 miles NNE of Libby, Lincoln County, Montana, USA, T34N R29W Sec 11, on 9 May 1988. Normal coloration for *Plethodon idahoensis* includes a pale gular patch and yellow dorsal stripe extending from the head through the tail. Sides, venter, and limbs are typically black with gray or white flecking (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 586 pp.). This individual lacked a gular patch and from head to mid-body, the dorsum was largely black with white flecks. Several yellow patches occurred on the dorsal thorax. The salamander was photographed and released.

ANURA

AGALYCHNIS CRASPEDOPUS (Amazon Leaf Frog). **REPRODUCTION.** Few observations of the reproductive biology of *Agalychnis craspedopus* have been reported. One study reported that eggs were observed to have been deposited above water-filled cavities in hollow logs that were ca. 1.0 m and 1.8 m above the ground. Eggs have also been found in muddy pools on bare ground in undisturbed primary forest of Amazonian Peru. (Hoogmoed and Cadle 1991. Zoologische Mededelingen 65:129–142). However, these frogs have not been reported to use water cavities in standing plank tree buttresses. Herein we report two such instances from the Departamento de Madre de Dios, Peru (specific locality available from ERW). This also represents the easternmost record for the genus *Agalychnis*.

On 29 December 2000 between 1630 and 1830 h, large, dark blue, almost black, tadpoles were observed swimming in a pool in a plank buttress of a "Mashinga" tree (Moraceae: *Ficus* sp.; 7.147 m DBH) in seasonally inundated forest (Tree #1). The pool was ca. 0.5 m deep with a water temperature of 27°C (Pool 1A). A sample of seven tadpoles was removed for identification and released several days later back into the pool. A second smaller (0.1 m deep) pool (Pool 1B) with similar appearing tadpoles was also discovered in the same buttress; it was not clear if the two pools were connected. Six clutches of eggs at varying stages of development were observed at Tree #1. One clutch was on the buttress itself overhanging Pool 1B; the others were overhanging Pool 1A. Four of the clutches at Pool 1A were stuck to the side of the buttress about 20 mm above the water surface. These clutches were at different stages of development and had approximately 14–20 eggs each. The other clutch was on a leaf of a vine growing on the branches of Tree #1, hanging 2.5 m above and directly over Pool 1A. At 1500 h on 31 December 2000, an adult male *Agalychnis craspedopus* (SVL 61.5 mm; 12.0 g) was observed on the tree buttress 0.5 m above Pool 1A, into which it jumped. This specimen was captured, photographed, preserved, and deposited in the Museo de Historia Natural of the Universidad Nacional Mayor de San Marcos, Lima, Peru (MHNSM 18537). The site was visited again on 1 January, 2002, at which time the clutch on the leaf above Pool 1A was gone and the four nests on the buttress around Pool 1A looked as if some had hatched, and the more developmentally advanced eggs had a yellow-green slimy growth. The clutch over Pool 1B was still present. Grunt calls, presumed to be those of *A. craspedopus*, were recorded later that evening (2100–2200 h: ERWA 1 365–421). On 4 January 2002, water in the pools had dropped and only the clutch above Pool 1B remained; a few

FIG. 1. The locations of five *Agalychnis craspedopus* clutches around a blank buttress pool of Tree 2.

grunt calls were heard. Between 2218 and 2313 h on 5 January, 2002, a second adult male of *A. craspedopus* (SVL 54.8 mm, 9.81 g) was calling 3–4 m above ground on a tree branch approximately 5 m south of Tree #1; at least three other males were heard. During 2100–2330 h on 6 January 2002, we returned to release the specimen and heard 3 or 4 *A. craspedopus* calling from high-up in the canopy. A snake (Colubridae, *Leptodeira*) was crawling down the vine and leaf where originally an egg clutch had been 2.5 m above Pool 1A.

Grunt calls presumed to be *A. craspedopus* were heard at another site in terra firma forest on 8 January 2001. This site was visited after 1400 h on 9 January 2001, and a another large "Mashinga" tree (Moraceae: *Ficus* sp.) (Tree 2) was found that contained a 23.5 cm deep pool, 0.5 m above the ground in the plank buttress. Tadpoles were present in the pool and five egg clutches were on the buttress and vegetation around the pool. The number of eggs and distance from the pool for each of these clutches are: 2 eggs, 1.26 m; 15 eggs, 1.94 m; 14 eggs, 1.63 m; 16 eggs, 0.33 m; and 7 eggs, 0.59 m. Grunt calls were heard on a return visit that evening.

These observations are the first to describe *A. craspedopus* using pools in tree buttresses for reproduction. Furthermore, the observations add significantly to the little that is known about the reproduction of this species.

BUFO FOWLERI (Fowler's Toad) and ***MALACLEMYS TERRAPIN TERRAPIN*** (Northern Diamondback Terrapin). **REFUGIA and NESTING.** In the context of a nesting and hatchling study of the diamondback terrapin during summer 2000 and 2001 in Bayville, New York, we recorded multiple observations of the use of terrapin nest excavations by the Fowler's toad. Our study site is a 1-ha flat, sandy plot adjacent to an estuarine marsh of Oyster Bay, on the north shore of Long Island.

In our study site, female terrapins frequently begin an excavation and abandon it before it is complete, moving several meters to another location. Such excavations, typically 5–10 cm deep, which we have termed "test holes," are common in our study site.

Once the female completes an acceptable nest, it is cylindrical, about 11–20 cm deep, and the egg chamber usually measures 4–10 cm diam (Montevecchi and Burger 1975. Amer. Midl. Nat. 94:166–178). In our study site, when the hatchlings emerge from the nest they often leave a conspicuous oval-shaped emergence hole, which is ca. 3–5 cm across at the surface and extends ca. 4–12 cm deep (Bossert and Draud, unpubl. data). Approximately 25% of the terrapin nests were predated by raccoons in our study site. This predatory action left a hole that was slightly larger in diameter than, and as deep as, the original egg chamber.

During September 2000 we examined 58 emergence holes and found Fowler's toads residing in 3 (5.2%). During June 2001 we examined 28 test holes and found 2 Fowler's toads (7.1%). In addition, we examined 20 raccoon-predated terrapin nests, and found 1 toad (5%). During September 2001, we examined 63 emergence holes and recorded 5 more resident toads (7.9%). Thus, over the two-season period, 6.5% of the 169 terrapin excavations examined had toads residing in them. Over the same two-season period, seven other toad observations were recorded in the study site (e.g., under various objects or hopping along the ground).

The Fowler's toads found residing in terrapin excavations ranged from 42–63 mm SVL. It is unknown if all 11 occasions were different toads, but from the locations, times, and sizes we believe that they were. In each case, a solitary toad was buried in the soft sandy soil at the bottom of the nest, head facing up. Our data do not allow us to comment specifically on the length of time the toads spent within the terrapin excavations, but in 2001, 2 of the 8 observed toads remained in the same excavation for at least 3 days. Since nest density is high in our study site (mean density = 2.22 nests /100 m^2), it is entirely possible that they would use several different excavations within their home range, which has been conservatively reported to range between 100 and 1000 m^2 (Clarke 1974. Amer. Midl. Nat. 92:257–274).

Bufo use various naturally occurring depressions for water conservation, crypsis, and thermoregulation, and Fowler's toads have been reported to use small mammal burrows (Clarke 1974, *op.cit.*), but to our knowledge this is the first published report of their use of turtle excavations. Fowler's toads are thought to dig into loose sand to hibernate and typically are not active at the surface after late September in our study area. Given our discovery of toads buried in terrapin excavations in late September (latest observation was 25 Sept 2001) we believe it is likely that in addition to using the excavations as refugia, they may also use them for hibernacula. Fowler's toads have also been observed in empty terrapin nests in Wellfleet, Massachusetts (Don Lewis, pers. comm.). It is unknown how widespread the use of empty turtle nests by Fowler's toads might be, but we speculate that wherever large populations of toads coincide with active turtle nesting areas, it is likely to be a common occurrence.

BUFO TERRESTRIS (Southern Toad). **PREDATION**. On 2 June 2002 I observed three different incidences of adult *Bufo terrestris* being depredated by giant water bugs (*Lethocerus* sp.: Belostomatidae) in a small temporary pond in Gainesville, Florida, USA. The insects seized the toads just posterior to the hind limbs. Two of the toads were male and were captured while calling at the waters surface. The third victim was a female. Although incapacitated, the female was in amplexus with a male that was apparently unaware of the insect attached just below him. All of the toads appeared to be breathing but were paralyzed and unresponsive. Giant water bugs are known predators of anuran larvae (Duellman and Trueb 1986. Biology of Amphibians, John Hopkins Univ. Press, Baltimore, 246 pp.; Peterson and Blaustein 1992. Copeia 1992:577–584; Relyea 2001. Ecology 82:541–554); however, predation on adult anurans is reported from only one other published account involving *Rana cascadae* (Nauman and Dettlaff 1999. Herpetol. Rev. 30:93). The observations reported in this note suggest that predation on adult anurans by giant water bugs may be common, thus making these insects significant predators on both

larval and adult anurans. Furthermore, many anurans are likely to only encounter giant water bugs at breeding sites where they may both reach high densities. The combined effects of predation on breeding adult anurans and their offspring by giant water bugs may have a significant impact on anuran populations.
